Accurate and continuous monitoring of cerebral blood flow is valuable for clinical neurocritical care and fundamental neurovascular research. Transcranial Doppler (TCD) ultrasonography is a widely used non-invasive method for evaluating cerebral blood flow¹, but the conventional rigid design severely limits the measurement accuracy of the complex three-dimensional (3D) vascular networks and the practicality for prolonged recording². Here we report a conformal ultrasound patch for hands-free volumetric imaging and continuous monitoring of cerebral blood flow. The 2 MHz ultrasound waves reduce the attenuation and phase aberration caused by the skull, and the copper mesh shielding layer provides conformal contact to the skin while improving the signal-to-noise ratio by 5 dB. Ultrafast ultrasound imaging based on diverging waves can accurately render the circle of Willis in 3D and minimize human errors during examinations. Focused ultrasound waves allow the recording of blood flow spectra at selected locations continuously. The high accuracy of the conformal ultrasound patch was confirmed in comparison with a conventional TCD probe on 36 participants, showing a mean difference and standard deviation of difference as $-1.51 \pm 4.34 \text{ cm s}^{-1}$, $-0.84 \pm 3.06 \text{ cm s}^{-1}$ and $-0.50 \pm 2.55 \text{ cm s}^{-1}$ for peak systolic velocity, mean flow velocity, and end diastolic velocity, respectively. The measurement success rate was 70.6%, compared with 75.3% for a conventional TCD probe. Furthermore, we demonstrate continuous blood flow spectra during different interventions and identify cascades of intracranial B waves during drowsiness within 4 h of recording.

Cerebral blood flow supplies oxygen and energy substrates and removes metabolic wastes to maintain proper brain functions. Continuous monitoring of cerebral haemodynamics enables screening and diagnosing brain disorders² as well as understanding neurovascular functions³. However, assessment of cerebral blood flow is challenging because cerebral vasculature is embedded deep inside the brain and protected by the skull. Various modalities to measure cerebral blood flow have been explored (Extended Data Table 1 and Supplementary Discussion 1), including positron emission tomography⁴, computed tomography⁵ and magnetic resonance imaging⁶, which all provide adequate spatial resolution but require bulky equipment that prohibits continuous use. Emerging thermal⁷, electrical⁸, and optical probes⁹ can be miniaturized for continuous monitoring, but these probes cannot provide sufficient spatiotemporal resolutions.

Transcranial Doppler (TCD) is widely used for cerebral haemodynamic monitoring because of its safety, low cost, portability, versatility and relatively high spatiotemporal resolutions (Supplementary

Table 1). However, conventional TCD probes have several limitations. First, these probes are rigid and need to be manually held by well-trained clinicians or affixed using bulky headsets for continuous monitoring¹. Slight misalignment between the ultrasound beam and the target vessel, often caused by hand movement, poor headset fastening or movement by the participant, can cause fluctuation, degradation or complete loss of signals². Therefore, the headset is usually very tight, causing discomfort, thus limiting the typical recording time to less than 30 min (ref. 10). Second, these probes usually use a single transducer or a linear array of transducers, which can only image part of the intricate three-dimensional (3D) network of cerebral arteries. Different operators may acquire signals from different segments of the 3D network, affecting repeatability and reproducibility¹ (Extended Data Fig. 1). Furthermore, manual probe tilting is required to identify the optimal angle for the acquisition of high-quality spectra, a routine process that is both time-consuming and heavily reliant on the expertise of the operator. To address these problems, volumetric imaging can be used to guide

target selection (Supplementary Fig. 1). Although two-dimensional (2D) matrix arrays can provide volumetric imaging, currently these probes have limited spatiotemporal resolutions because of technical barriers in probe fabrication and data acquisition^{11,12} (Supplementary Discussion 1).

Wearable ultrasound devices enable comfortable contact with the skin surface for sensing physiological signals in deep tissues^{13–17}. However, probing inside the brain is challenging because of the strong signal attenuation (Supplementary Fig. 2 and Supplementary Discussion 2) and phase aberration (Supplementary Fig. 3 and Supplementary Discussion 3) caused by the skull. Furthermore, existing wearable ultrasound devices provide only one-dimensional (1D) signals¹⁸, 2D images¹⁹ or 3D images by inaccurate integration and extrapolation of multiple 2D image slices²⁰. Here we report the first conformal ultrasound patch for accurate and continuous monitoring of cerebral blood flow in 3D (Supplementary Discussion 4). We use low-frequency ultrasound waves to reduce the skull-induced signal attenuation and phase aberration²¹. We add a copper mesh shielding layer to the device and adopt an ultrafast imaging technique to insonate the entire 3D region, which substantially improves the signal-to-noise ratio^{22,23}. This technology represents a powerful platform for both clinical and fundamental haemodynamic studies.

Device design and characterizations

To minimize acoustic attenuation and phase aberration, four transcranial windows (temporal, orbital, submandibular and suboccipital) are commonly used for TCD²⁴ (Supplementary Fig. 4). These windows are relatively small (about 5 cm² in adults)¹, requiring a compact device design. By contrast, the cerebral arterial network has several major components, including the anterior cerebral arteries (ACA), middle cerebral arteries (MCA), posterior cerebral arteries (PCA), ophthalmic arteries, internal carotid arteries (ICA), basal artery and vertebral arteries (Supplementary Discussion 5). Most of these arteries are deep (around 40–100 mm) and widely distributed inside the brain¹ (Fig. 1a), requiring devices with a wide ultrasound field (Supplementary Fig. 5). Therefore, we used diverging waves to image the entire arterial network and focused waves to monitor local blood flow spectra at target arterial sections (Fig. 1b and Methods). Diverging waves extend the ultrasound field from a limited acoustic window (12 mm × 12 mm) to a much larger region (about 60 mm × 60 mm at 50 mm depth in this work), which allows for simultaneous insonation of multiple cerebral arteries. Focused waves minimize unnecessary ultrasound exposure to surrounding tissues for long-term monitoring of blood flow spectra.

We built a 16 × 16 matrix array with a 750- μ m pitch and a 2-MHz centre frequency (Methods and Supplementary Discussion 6). The choice of such a low frequency reduces signal attenuation and phase aberration and thus enhances transcranial penetration depth¹ (Supplementary Discussions 2 and 3). The pitch is comparable to the ultrasound wavelength (that is, 770 μ m in soft tissues at 2 MHz), enabling a large tilting angle of the ultrasound beam in 3D (Supplementary Fig. 6). The matrix array has an aperture of 12 mm × 12 mm, similar to that of established TCD probes^{25,26}, which enables insonation through the skull and focusing on deep targets¹². Five layers of serpentine interconnections are used to address the 256 elements individually (Fig. 1a and Supplementary Fig. 7). The matrix array has excellent properties such as high electromechanical coupling coefficient, and negligible crosstalk, resulting in high sensitivity to Doppler shift (Methods and Supplementary Fig. 8). We designed a serpentine copper mesh as an electromagnetic shielding layer, which increased the signal-to-noise ratio on average by 5 dB (Methods and Supplementary Fig. 8). Encapsulation of the entire device by silicone elastomer allows for electrical insulation and conformal contact on various surfaces (Fig. 1c, Supplementary Figs. 9 and 10). The final device is 1.3 mm thick, 20 mm wide and 28 mm long, with a total weight of 0.945 g.

The ultrasound intensity of the device was measured in a water tank (Methods, Extended Data Fig. 2 and Supplementary Discussion 7). We limited the maximum derated mechanical index and derated spatial peak temporal average intensity of all ultrasound transmissions in this work to about 0.7 and 370 mW cm⁻², respectively. These values are well below the Food and Drug Administration Track 1 maximum recommended levels for TCD applications (that is, 1.9 and 720 mW cm⁻², respectively)²⁷. After penetrating through a temporal bone specimen, the measured maximum derated spatial peak temporal average intensity was reduced by approximately 83% to about 63 mW cm⁻² (Extended Data Fig. 2 and Supplementary Fig. 11). For orbital window scans, the maximum mechanical index and derated spatial peak temporal average intensity were reduced to conform to the Food and Drug Administration Track 1 recommended maximum levels for ophthalmic scans (0.23 and 17 mW cm⁻², respectively)²⁷.

To characterize its thermal effect, we attached the device to the scalp of a normal human volunteer and activated the device for 4 h. The maximum temperature rise on the skin surface was less than 1 °C (Supplementary Fig. 12). Furthermore, for estimated temperature changes of internal tissues during prolonged ultrasound exposure, we calculated the thermal index²⁷, the ratio between the incident acoustic power and the power required to raise the tissue temperature by 1 °C (Supplementary Discussion 7), which were 0.62 for soft tissue thermal index and 0.38 for cranium thermal index. According to an official statement of the American Institute of Ultrasound in Medicine, for a thermal index less than or equal to 1.5, there is no time limit for adult transcranial ultrasound because any thermal exposure would be below thresholds for bioeffects ([https://www.aium.org/resources/official-statements/view/recommended-maximum-scanning-times-for-displayed-thermal-index-\(ti\)-values](https://www.aium.org/resources/official-statements/view/recommended-maximum-scanning-times-for-displayed-thermal-index-(ti)-values)).

Volumetric ultrafast imaging

The temporal window is the most widely used imaging window for TCD and has become the standard for cerebral artery assessment¹ (Supplementary Fig. 13). Through the temporal window, we can achieve ultrasound insonation of the terminal ICA (TICA), which delivers blood from the neck to the major arteries in the brain, as well as the ACA, MCA and PCA, which deliver blood to most of the four brain lobes (frontal, parietal, temporal and occipital).

The cerebral arteries can be mapped by ultrafast ultrasound data acquisition followed by subsequent volumetric image reconstruction (Methods). Compared with conventional volumetric Doppler imaging, this method substantially enhances the signal-to-noise ratio (Supplementary Fig. 14). The 256 elements are activated to emit five diverging waves at different insonation angles at a 3,000-Hz pulse repetition frequency (Fig. 2a). For all insonation angles, the backscattered raw radiofrequency signals are saved. During subsequent image reconstruction, beamforming and coherent compounding (Supplementary Discussion 8) are performed on the raw signals, which allows the backscattered signals from all insonation angles to be recombined (Fig. 2a). Because signals from different insonation angles produce images of the same target object but different artefacts, signal recombination causes constructive summation of the target object but destructive summation of artefacts, boosting the object to background contrast²². A spatiotemporal clutter filter (for example, singular value decomposition in this work) separates tissue motion signals from blood flow signals in the compounded data based on the difference in their spatiotemporal coherences²⁸ (Supplementary Discussion 9). Additional filters are used to suppress the noise and enhance the vascular structures^{29–31}. Finally, the filtered data are used to reconstruct a volumetric power Doppler image (Fig. 2a). The diverging waves and the multi-angle compounding method provide a wide ultrasound field, which simultaneously insonates the bilateral ACA, MCA, PCA, and TICA, mapping a large vascular

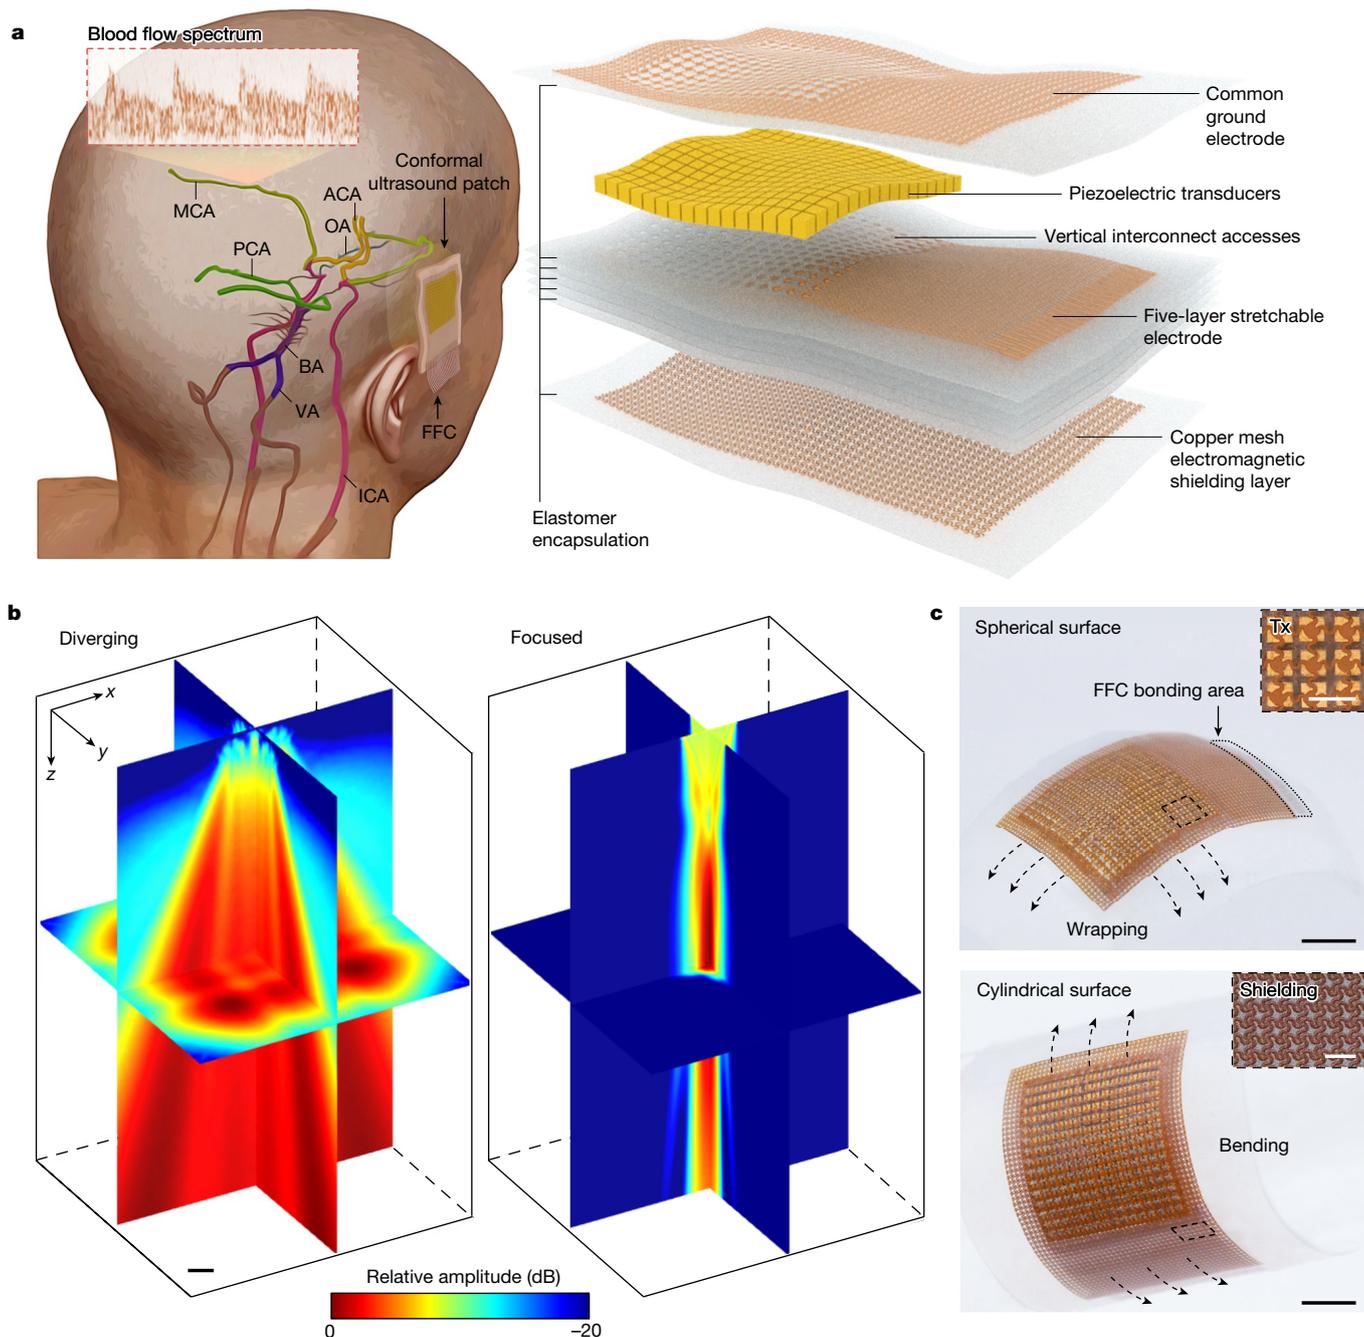

Fig. 1 | Overview of the conformal ultrasound patch for TCD. **a**, Schematic of the working configuration and patch structure. The patch is attached to the scalp for volumetric mapping of the major arteries in the brain⁴⁸. Blood flow spectra of different target arteries are recorded. The patch consists of a 16×16 array of piezoelectric transducers connected by a five-layer stretchable electrode and a common ground electrode. A copper mesh is used as an electromagnetic shielding layer to enhance the signal-to-noise ratio. The entire device is encapsulated by a waterproof and biocompatible silicone elastomer. **b**, Simulation results of diverging and focused ultrasound fields based on 2D matrix array

beamforming. The maximum derated spatial peak temporal average intensity of the focused ultrasound field is around 370 mW cm^{-2} for spectra monitoring, much below the threshold recommended by the Food and Drug Administration (720 mW cm^{-2}) (ref. 27). The simulation was performed using an open-source Matlab toolbox Field II. **c**, Optical images of the patch on a spherical surface and a cylindrical surface. The insets show the magnified transducer array (top) and the electromagnetic shielding layer (bottom). network (Fig. 2b for participant 1 and Supplementary Figs. 15–49 for participants 2–36).

We recorded volumetric power Doppler images during a carotid compression test and captured the flow variations in different arterial segments, which helped in identifying different cerebral arteries (Fig. 2c). Compressing the left common carotid artery mostly caused a decrease in flow in the left TICA and left MCA, a change in flow direction

in the left ACA, an increase in flow in the left PCA and an increase in flow in most of the contralateral vessels (Supplementary Discussion 5). To semi-quantitatively evaluate the vascular network capacity, we evaluated the changes in the amplitude of the power Doppler signal of selected representative landmarks in each arterial segment. The results indicate that the collateral circulation could be recorded reliably (Fig. 2d and Extended Data Fig. 3).

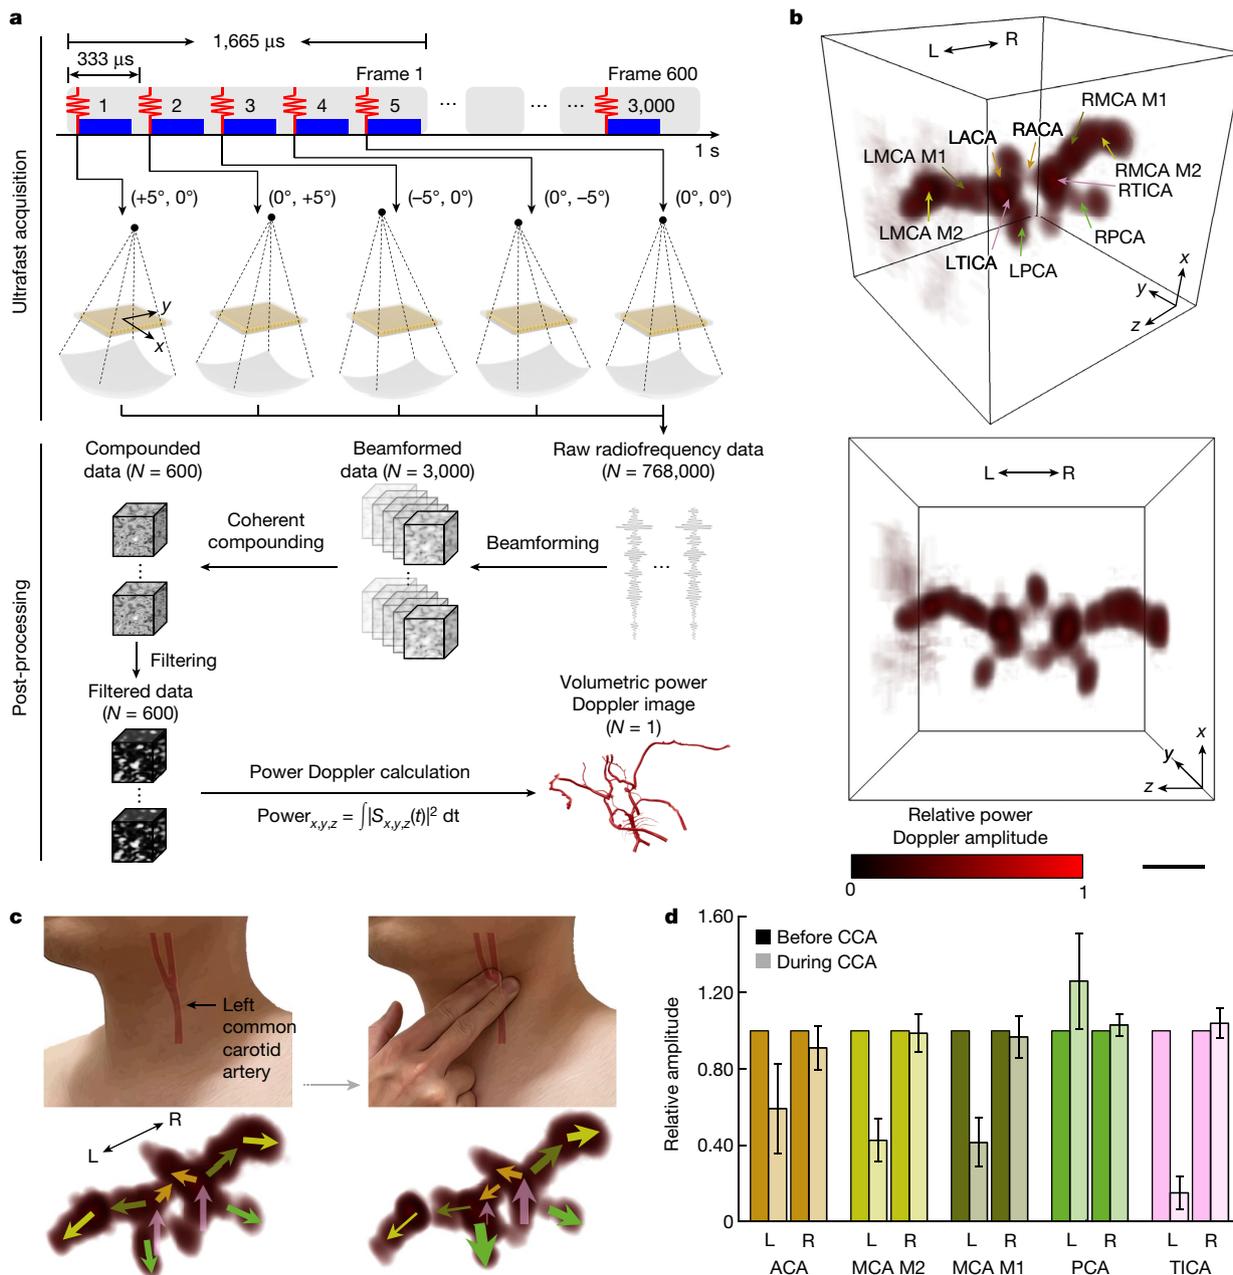

Fig. 2 | Volumetric ultrafast power Doppler imaging. **a**, Schematic of the imaging process. In ultrafast acquisition, five diverging waves with different insonation angles are quasi-simultaneously transmitted at a 3,000-Hz pulse repetition frequency. In post-processing, the acquired raw radiofrequency data go through beamforming, coherent compounding, singular value decomposition filtering and power Doppler calculation to reconstruct a volumetric power Doppler image. **b**, Different views of the volumetric power Doppler image of major cerebral arteries from participant 1 in a $60 \times 60 \times 60$ mm³ region, acquired through the temporal window. Volumetric power Doppler images from participants 2–36 can be found in Supplementary Figs. 15–49. **c**, Comparison of volumetric power Doppler images before and during the left common carotid artery being compressed. The colour and thickness-coded arrows indicate the directions and magnitudes of blood flow in different

arterial segments. **d**, Bar graph of compression carotid artery test. The power Doppler amplitudes of representative landmarks of bilateral arterial segments change accordingly before and during the compression of the left common carotid artery. The measurements were repeated three times on six participants. Error bars indicate 1 s.d. of the measurements. Note that individual anatomical variations, such as hypoplasia or aplasia of certain arteries, can affect these results⁴⁹. The hypoplasia or aplasia arteries are observed in two of the six participants in this study. Each bar is colour-coded for different arterial segments (cider for ACA, xanthic for MCA M2, juniper for MCA M1, Kelly green for PCA and carnation pink for TICA). To better evaluate the relative change before and after compression, we normalized the results before compression and only considered the relative change of the blood flow during compression. L, left; R, right; CCA, compressing carotid artery. Scale bar, 10 mm (**b**).

Data processing and validation

Blood flow measurements by the conformal ultrasound patch were validated with a conventional TCD probe. We chose the circle of Willis as the model, which is composed of several major arteries that provide

blood supply to the entire brain¹. It has widespread branches, so the circle of Willis is usually measured through all four transcranial windows²⁴. Each window targets different arterial segments (Supplementary Table 2): the temporal is best for the ACA, MCA M2, MCA M1, PCA and TICA; the orbital for the ophthalmic arteries and ICA siphon;

It includes the ultrasound patch connected to a Verasonics system by shielded (3304BC-S, 3 M) cables. The host computer controls the Verasonics system for data acquisition and processing. The blood flow spectrum is displayed on the monitor. **c**, Examples of blood flow spectra recorded from representative arterial segments from participant 1 by using the ultrasound patch. The spectra share the same scale bars. Blood flow spectra from participants 2–36 can be found in Supplementary Figs. 15–49. **d–f**, Bland–Altman plots of peak systolic velocity (**d**), mean flow velocity (**e**) and end diastolic

velocity (**f**) measured by the ultrasound patch and a conventional TCD probe on 36 participants. Solid blue lines are the mean differences in the measurements between the two modalities. Solid red lines are 95% limits of agreement (that is, 1.96 s.d. above and below the mean differences), and black dash lines are the zero difference of the measurements between the two modalities. Each plot has 762 data points that are colour-coded for different arterial segments (that is, cedar for ACA, dark cyan for ophthalmic arteries (OA), xanthic for MCA M2, juniper for MCA M1, boysenberry for basal artery (BA), blueberry for vertebral arteries (VA), hibiscus for ICA, Kelly green for PCA, magenta for ICA siphon and carnation pink for TICA). FFC, flat flexible cable; L, left; R, right; A, anterior; P, posterior. Scale bar, 2 cm (**a**).

the submandibular for the ICA; and the suboccipital for the basal artery and vertebral arteries (Fig. 3a). The setup consists of the conformal ultrasound patch linked to a commercial ultrasound machine (Vantage 256, Verasonics) with shielded cables for signal transmission, controlled by a host computer for data acquisition and processing (Fig. 3b).

We developed codes for Doppler processing to acquire high-resolution blood flow spectra (Fig. 3c for participant 1 and Supplementary Figs. 15–49 for participants 2–36) with functions such as automatic spectral envelope tracking, sample volume customization, and audio (Supplementary Discussion 10). The recorded spectra have

Table 1 | Demographics of participants

Characteristics	n (%) or mean ± s.d.

Cerebrovascular disease	1 (2.8)
Biometrics	Mean ± s.d.
Age (years)	52.92 ± 18.74
Height (cm)	167.44 ± 9.25
Weight (kg)	68.92 ± 11.72
Body mass index	24.46 ± 2.80

This table presents an overview of the demographic information for all participants in this study. Details include sex, race/ethnicity, underlying conditions, age, height, weight and body mass index, providing context for the diversity of the participants, which ensures that the findings of the study are broadly applicable.

a temporal resolution around 200 Hz, a velocity resolution of less than 0.01 cm s⁻¹, and a 128-colourmap of Doppler signal intensities, which are similar to the performance of the latest conventional TCD system (<https://viasonix.com/products/transcranial-doppler/>). This enables us to correlate variations in blood flow velocities to the corresponding cardiac phases (Supplementary Fig. 50). Spectral envelope tracking provides peak systolic velocity and end diastolic velocity, which enables the computation of mean flow velocity, pulsatility index and resistive index (Methods and Extended Data Fig. 4). Sample volume customization can provide blood flow distribution across the entire target arterial segment, which is valuable for identifying pathologic turbulent flow (Supplementary Discussion 11) in the low-velocity zone² (Supplementary Fig. 51). Real-time audio provides convenience for clinical training and diagnostics (Supplementary Video 1).

For this comparison study between the conformal ultrasound patch and a conventional TCD probe, we have collected blood flow velocities of 10 arterial segments from 36 adult volunteers for three times to ensure the results are reliable and reproducible (Table 1 and Methods). Intrinsically, a complete circle of Willis is observed in only about 30% of the population³². Moreover, participants with specific demographics and medical history tend to have abnormal cerebral arteries and may exhibit thicker, or even inaccessible, skull windows²⁴. As a result, both the conventional probes and the ultrasound patch may encounter difficulties in detecting some or all cerebral arteries (Extended Data Table 2 and Supplementary Discussion 12).

Bland–Altman plots show that the mean differences and standard deviations (s.d.) of the differences between these two devices are -1.51 ± 4.34 cm s⁻¹, -0.84 ± 3.06 cm s⁻¹, -0.50 ± 2.55 cm s⁻¹, -0.0101 ± 0.0485 , and -0.0040 ± 0.0186 for peak systolic velocity, mean flow velocity, end diastolic velocity, pulsatility index and resistive index, respectively (Fig. 3d–f, Supplementary Fig. 52 and Supplementary Discussion 13). These biases are much smaller than these metrics per se, indicating good agreement between these two devices. To delve

deeper into our results, we apply scatter plots for a more thorough analysis (Supplementary Figs. 52 and 53). Notably, the squared correlation coefficients for all velocity parameters and indices exceed 0.9. This strong correlation underscores the consistency in the readings between these two devices.

Monitoring under different scenarios

The brain can regulate its blood flow to meet physiological demands (Supplementary Discussion 14). Surveillance of these regulations can be used to evaluate neurological functions. The conformal ultrasound patch was used to measure (using the temporal window) MCA and PCA flows, which dominate the supply of blood to the brain. The motion tolerance of the device was determined to be within about $\pm 20^\circ$ with head roll, yaw and pitch (Supplementary Fig. 54). Rotating the head beyond this range may shift the alignment between the ultrasound beam and arteries, resulting in signal degradation or loss. We then asked the participants to conduct four different activities that modulated haemodynamics in specific cerebral arteries (Methods and Supplementary Fig. 55). Each activity was repeated 15 times to minimize interference of confounding factors.

The handgrip involves the contraction of the forearm muscles that activate the sympathetic nervous system, leading to an increase in blood supply to the brain and therefore the contralateral MCA blood flow velocity³³. The test consists of three phases: resting baseline, right handgrip and recovery. The left MCA mean flow velocity rose rapidly at the beginning of the handgrip, then slowly plateaued at around 119% baseline velocity when the handgrip was maintained. The flow velocity decreased swiftly to 95% baseline velocity immediately after the handgrip was released and gradually reached a plateau towards the end of the recovery phase (Fig. 4a).

The Valsalva manoeuvre provides an estimate of the autoregulatory capacity³⁴. It changes the intrathoracic pressure, which affects the venous return, cardiac output, blood pressure and, therefore, cerebral blood flow. We monitored the left MCA mean flow velocity during four sequential phases. In phase I, the participants inhaled deeply; the intrathoracic pressure increased, which led to a decrease in the heart rate and a slight (about 5%) increase in the cerebral blood flow. In phase IIa, the participants held their breath; the venous return decreased, which led to a decrease in the heart rate and around 12% drop in the blood flow. In phase IIb, the baroreflex was activated, which increased the heart rate and partially restored the blood flow. In phase III, the participants exhaled; blood was refilled to the pulmonary vasculature, leading to an increase in the heart rate and slight variations (an increase in most participants) in the blood flow. Finally, in phase IV, the participants resumed normal breathing; the venous return increased, resulting in a decrease in the heart rate and subsequent overshoot (about 118%) of the cerebral blood flow. Once the venous return went back to normal, the blood flow dropped back to the baseline (Fig. 4b).

Word generation is commonly used in functional TCD to understand language processing and production. In this activity, a cue tone was used for auditory signal stimulation, and then a letter was given to the participants. The participants were asked to use the letter to generate words and orally report them after a second auditory signal stimulation. The recorded left MCA mean flow velocity showed a rise (approximately 5%) from the baseline on hearing the tone and after a letter was provided. Activation of the language centre of the brain led to an increased demand for cerebral blood flow in the dominant hemisphere³⁵. The velocity remained at an average of about 110% baseline during word generation and continued to increase (by about 18%) when the participant was reporting the words (Fig. 4c).

Visual stimulation can change the blood flow in the visual cortex³⁶. We monitored the PCA that supplies blood to the primary vision centre in the brain (that is, the occipital lobe) when the participants

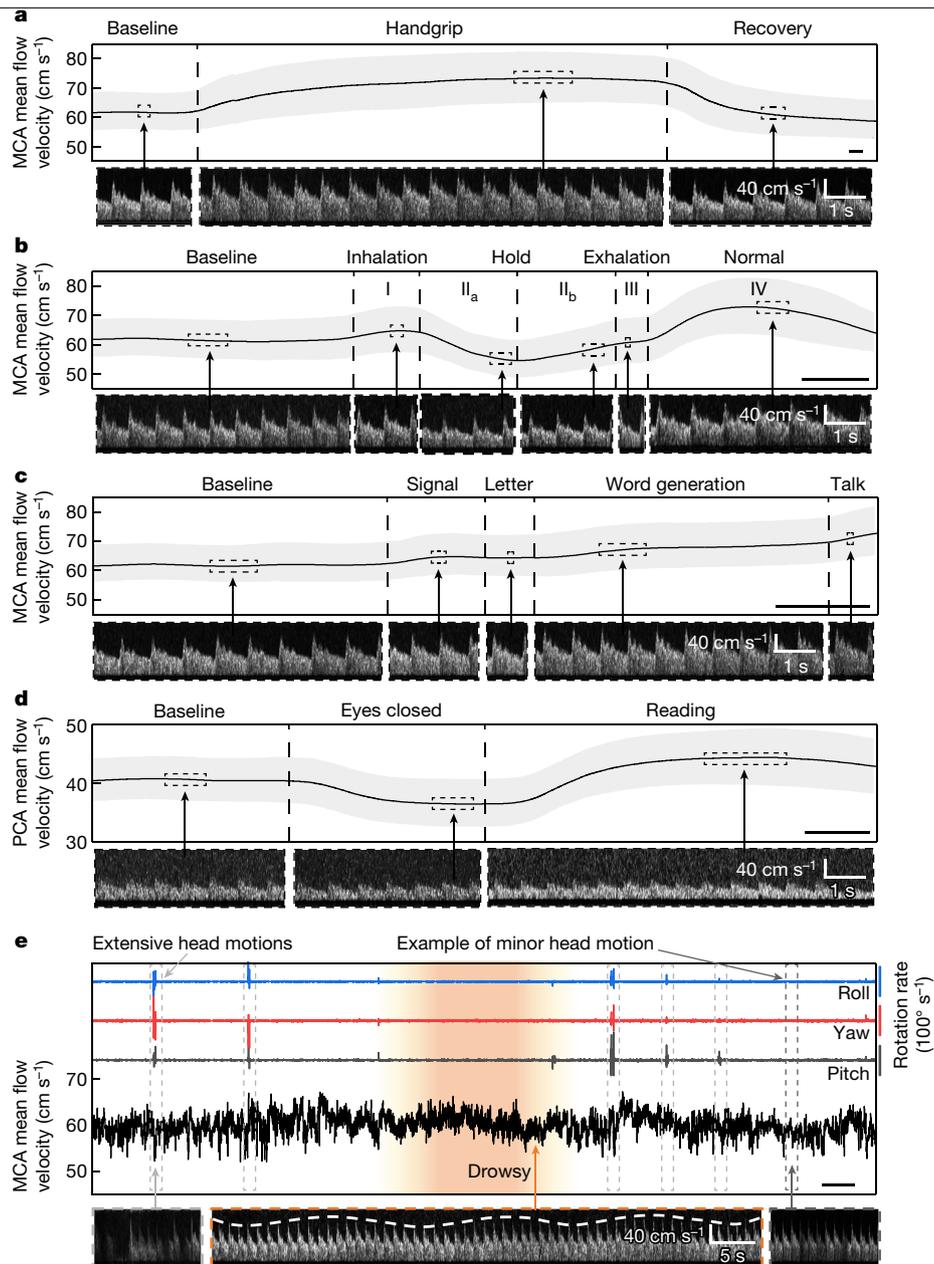

Fig. 4 | Monitoring of cerebral haemodynamics under different scenarios. **a–d**, Mean blood flow velocities of target arteries recorded during different activities (handgrip **(a)**, Valsalva manoeuvre **(b)**, word generation **(c)** and visual stimulation **(d)**). The measurements for each activity were repeated 15 times on six participants. Solid black lines are the average results and grey regions denote ± 1 s.d. The corresponding spectra are snapshots showing representative flow characteristics in each phase of the activity. The blood flow spectra share the same scale bars. **e**, The mean flow velocity in the MCA and the corresponding gyroscope data during a continuous 4-h recording. Rotation rates of rolling,

yawing and pitching are denoted by blue, red and black lines, respectively. Transient signal loss periods due to extensive head motions and a spectrum during this period are labelled with light-grey dashed boxes. An example of minor head motion and a spectrum during this period are labelled with dark-grey dashed boxes. The participant felt drowsy at around 2 h into the recording. The figure labelled with an orange dashed box highlights the flow characteristics during this period. Intracranial B waves with a frequency of about three cycles in 1 min are labelled by a white dashed line. The blood flow spectra share the same scale bars. Scale bars, 5 s (**a–d**); 10 min (**e**).

closed their eyes and then opened their eyes to read. The left PCA mean flow velocity decreased to around 90% baseline with eyes closed and gradually increased until it peaked (around 110% baseline) with reading (Fig. 4d).

These transient cerebral haemodynamic changes are the result of the activities of the participants and can be impaired or inhibited if pathological conditions exist³⁷. The recorded cerebral blood flow profiles during these activities follow similar trends as those measured by conventional TCD probes^{33–36}, indicating a potential clinical benefit for monitoring cerebral haemodynamics using the conformal patch.

Because it allows hands-free, wearable measurements, the conformal ultrasound patch is particularly useful for prolonged surveillance (Extended Data Fig. 5). For example, intracranial B waves during sleep are closely related to the glymphatic system activities, which is important for toxic waste by-product removal in the brain and disease recovery^{38,39} (Supplementary Discussion 15). These events are accompanied by slow, spontaneous oscillations in the cerebral blood flow velocity (that is, B waves) at 0.3–4 cycles per minute⁴⁰. With the conformal ultrasound patch at the temporal window, we monitored the cerebral blood flow spectra in the MCA in a participant for 4 h continuously (Fig. 4e).

The recording has a high signal-to-noise ratio, except for transient signal fluctuations during extensive head motions (Fig. 4e and Supplementary Fig. 56). Minor head motions, which the participant naturally made, does not significantly affect the signal quality (Fig. 4e). A cascade of B waves was identified when the participant felt drowsy (Fig. 4e). Prolonged surveillance is also valuable for cerebral emboli monitoring and therefore embolic stroke prevention. Evidence suggests that extending the recording time can capture more patients positive for an embolic signal¹⁰. The conformal ultrasound patch could detect flowing emboli in a phantom (Supplementary Fig. 57), demonstrating the promise of prolonged recording using the conformal patch in a clinical setting.

Discussion

TCD is a powerful ultrasound modality for neurovascular diagnostics and research, but the conventional form factor limits continuous measurements of cerebral arteries and can only image 1D or 2D planes of the complex 3D network. To develop a conformal ultrasound patch for continuous TCD application, we have designed a soft 2D matrix array for volumetric imaging and electronically locating target arterial segments from the complex 3D cerebral arterial network. The conformal ultrasound patch coupled with ultrafast signal acquisition enables volumetric imaging of the cerebral arterial network and simplifies the blood flow data acquisition process from target vessels. Using the reconstructed volumetric image, we can electronically focus the low-intensity ultrasound beam to acquire cerebral blood flow measurements from various segments of the 3D arterial network. The design notably minimizes operator dependency and enhance motion tolerance in comparison to conventional TCD probes (Supplementary Discussion 16). Moreover, a comprehensive survey of feedback from all participants indicated that a majority (69.4%) prefer the conformal ultrasound patch for its comfort (Supplementary Fig. 58). With these advantages, we demonstrate not only blood flow measurements from different segments of the major cerebral arteries and transcranial monitoring of cerebral haemodynamics under different scenarios (for example, carotid compression test, handgrip, Valsalva manoeuvre, word generation and visual stimulation) but also long-term monitoring during drowsiness with minimal signal loss. These results have notable implications for both clinical diagnostic tools for brain disorders and medical research on neurovascular functions (Supplementary Discussion 16).

The synergy between the conformal ultrasound patch and ultrafast volumetric reconstruction enables haemodynamics monitoring in complex 3D vascular networks. Therefore, apart from cerebral arteries, this technology can also be used to study the complex haemodynamics in other clinically important vessels, such as the carotid bifurcation. The structural morphology of these arteries induces turbulent blood flow, prone to atherosclerosis and emboli generation⁴¹. The conformal ultrasound patch can detect both gas and solid emboli (Supplementary Fig. 57), potentially enabling early detection for timely intervention before severe pathological progression in major arteries.

This study primarily focuses on the development of the front-end ultrasound patch, the related ultrafast imaging algorithms and the validation of their applications in transcranial volumetric imaging and cerebral blood flow monitoring. With future development, the performance of the device and functionality could be further enhanced.

First, the conformal ultrasound patch has limited spatial resolution. Signals from major cerebral arteries can be obtained, but the patch neglects information from arterioles, venules and capillaries. Obtaining signals from all vessels can provide a more holistic insight into the cerebrovascular system. Thus, to improve the spatial resolution, contrast agents such as microbubbles⁴² may be needed to generate much higher amplitude echoes compared with the surrounding tissues (Supplementary Discussion 17). Ultrafast ultrasound localization microscopy can potentially be adopted to overcome the diffraction limit, enabling super-resolution transcranial imaging and full reconstruction of deep

vascular systems down to the level of capillaries^{43,44}. Furthermore, by using harmonic imaging, the incident ultrasound waves can drive the microbubbles to vibrate nonlinearly, generating strong harmonic components in echoes⁴⁵ (Supplementary Discussion 18). Moreover, time reversal can be used to calculate precise time delays on each element of the transducer array and thus partially compensate for the phase aberration of the skull⁴⁶.

Second, the volumetric image reconstruction was post-processed subsequently after data acquisition. This post-processing time may hinder the workflow of the clinicians when needing to dynamically target different segments of the cerebral arterial network in real time. Improvement in volumetric reconstruction speed can be realized by a multi-threaded process with much higher computational power for image reconstruction. The calculation and image rendering processes could be highly parallelized and optimized for real-time imaging⁴⁷, which may be valuable for understanding the real-time functional connectivity of the brain.

Third, the conformal ultrasound patch was connected to the Verasonics system for all data acquisition processes. Volumetric imaging requires a relatively high-power supply to successfully transmit and receive ultrasound waves through the transcranial windows into the deep brain. Moreover, the ultrafast data acquisition process and long-term measurements of blood flow velocity can generate a large dataset (for example, 1–5 GB), which requires a powerful system for fast data transfer and processing. Back-end systems based on customized printed circuit boards or application-specific integrated circuits can significantly miniaturize the control system with reduced power consumption to provide higher freedom of movement for long-term wearability¹⁶ (Supplementary Discussion 19).

Fourth, transient signal fluctuations were observed in the long-term recording due to ultrasound beam misalignment to the target during extensive head motions. Machine-learning algorithms can be used to identify signal loss, automatically track the targeted arterial segment, eliminate occasions of signal loss and improve reliability in clinical utility during continuous measurements.

Finally, all participants in this study were healthy without severe neurological pathologies related to cerebral haemodynamics. Further testing across large populations, including particularly those patients with neurovascular conditions, such as vasospasm, stenoses, aneurysms and embolism, can potentially enable diagnostic parameters for the early detection of major neurological pathologies.

Methods

Device fabrication

Electrode design and patterning. The electrode is composed of a common ground electrode, a five-layer stretchable electrode and a copper mesh electromagnetic shielding layer. First, polyimide (poly(pyromellitic dianhydride-co-4,4'-oxydianiline) amic acid solution, PI2545 precursor, HD Microsystems) was spin-coated on copper sheets (Oak-Mitsui) at 4,000 rpm for 60 s, followed by soft baking on a hotplate at 100 °C for 3 min and subsequently at 150 °C for 1 min, and then hard baking in a nitrogen oven at 300 °C for 1 h, yielding a 2- μ m thick polyimide layer coated on 20 μ m thick copper sheets.

Polydimethylsiloxane (Sylgard 184 silicone elastomer) was then spin-coated at 3,000 rpm for 60 s on a glass slide and cured in an 80 °C oven as a temporary substrate for electrode transfer. To improve bonding, the polyimide-coated copper sheets and the polydimethylsiloxane-coated glass slides were activated by ultraviolet light (PSD series Digital UV Ozone System, Novascan) for 3 min.

The polyimide-coated side of the copper sheet was then attached to the polydimethylsiloxane-coated glass slide. The bilayer copper/polyimide film was laser ablated (Laser Mark's, central wavelength, 1,059–1,065 nm; power, 0.228 mJ; frequency, 35 kHz; speed, 300 mm s⁻¹; and pulse width, 500 ns) following electrode patterns designed with AutoCAD (Autodesk) (Supplementary Fig. 7).

Electronic packaging. On two separate glass slides, polymethyl methacrylate (495PMMA, Kayaku Advanced Materials), serving as a sacrificial layer, was spin-coated at 2,000 rpm for 60 s and cured at 80 °C for 30 min. Then, a 12- μ m thick silicone (Ecoflex-0030, Smooth-On) was spin-coated at 4,000 rpm for 60 s and cured at room temperature for 2 h.

To assemble the device, a water-soluble tape (5414 Transparent, 3 M) was used for transfer printing the ground electrode to an Ecoflex-coated glass slide and the copper mesh electromagnetic shielding layer to another Ecoflex-coated glass slide. The water-soluble tape was then removed by immersing it in 80 °C water for 30 min. Conductive epoxy (Von Roll 3022 E-Solder, EIS) was placed on the 256 bonding pads of the island-bridge layout of the common ground electrode. After that, the matrix array of 1–3 composites (Del Piezo Specialties) was bonded to the bonding pads by curing a conductive epoxy for 8 h at room temperature and then 2 h at 40 °C to avoid high-temperature-induced depolarization of the 1–3 composites.

On the glass slide with the copper mesh electromagnetic shielding layer, sequential transfer printing of the five-layer stretchable electrode was done, and it was stacked one on top of another by water-soluble tape. Each layer was bonded to a flat flexible cable (Premo-Flex FPC Jumper, Molex) using solder paste (Sn₄₂Bi_{57.6}Ag_{0.4} (melting point, 138 °C)) and spin-coated with a 25- μ m thick Ecoflex layer at 2,200 rpm for 60 s and cured at room temperature for 2 h. Laser ablation was used to create vertical interconnect accesses through the Ecoflex layers to expose the 256 bonding pads in the five-layer stretchable electrode⁵⁰. Then, this glass slide was bonded to the 1–3 composite on the other glass slide using conductive epoxy followed by curing.

Finally, the gaps between the two glass slides were filled with Ecoflex followed by curing at room temperature. The glass slides were removed by dissolving the polymethyl methacrylate in acetone to release the conformal ultrasound patch.

Acoustic field simulation

We simulated the diverging and focused ultrasound beams using an open-source Matlab toolbox Field II. The medium was set as uniform with a sound speed of 1,540 m s⁻¹ and a density of 1,000 kg m⁻³. The centre frequency was set to 2 MHz, the same as that of the real probe. We applied the built-in function, 'xdc_2d_array', to create the transducer

array. The transmission time delay of each transducer element could be individually set to emit a diverging beam or a focused beam.

Device performance characterizations

A network analyser (Hewlett-Packard 4195 A) was used to measure the electrical impedance and phase angle of each transducer in the device (Supplementary Fig. 8). Based on the electrical impedance graph, the resonant frequency (f_r), the frequency with the lowest electrical impedance, and anti-resonant frequency (f_a), the frequency with the highest electrical impedance, of the transducers were mapped (Supplementary Fig. 8). The effective electromechanical coupling coefficient (k_{eff}) was calculated by

$$k_{\text{eff}} = \sqrt{1 - \frac{f_r^2}{f_a^2}} \quad (1)$$

The pulse-echo response and bandwidth of the device were characterized (Supplementary Fig. 8). An aluminium block was placed 8 cm away from the device in a water tank. The back-end system (Vantage 256, Verasonics) was used to obtain raw radiofrequency signals by transmitting and receiving ultrasound pulse waves. Fast Fourier transform in Matlab R2021a was used to transfer the signals into the frequency domain.

Crosstalk between adjacent transducer elements was characterized by changing the transmitting frequencies and activation voltages (Supplementary Fig. 8). A sinusoidal peak-to-peak voltage of 15 V was applied by a functional generator (3390, Keithley) to excite one of the elements with different frequencies from 1 MHz to 3 MHz. Moreover, we used a 2-MHz transmission with activation voltages from 5 V to 25 V. The reference voltages received by adjacent elements were measured. Then, the crosstalk was calculated by

$$\text{Crosstalk} = 20 \log \left(\frac{\text{Reference voltage of the adjacent element}}{\text{Activation voltage of the excited element}} \right) \quad (2)$$

The signal-to-noise ratio with and without the copper mesh electromagnetic shielding layer was tested with a 1-mm thick thread underwater (Supplementary Fig. 8).

Safety-measurement procedures

To evaluate the safety of the device, the acoustic exposure was evaluated using a 3D ultrasound mapping system (AIMS III hydrophone scanning system, ONDA) following the provided calibration procedures. We used a calibrated hydrophone (Model HNP-0400, ONDA) to scan the ultrasound field in 3D in a water tank (Extended Data Fig. 2). The hydrophone was connected to an oscilloscope (PicoScope 5244A, ONDA), and software (Soniq v.5.3.1.0, ONDA) was used to control the scanning. We scanned a zone of 60 × 60 × 100 mm³ below the device with a spatial resolution of 0.1 mm with and without a formalin-fixed temporal bone specimen (about 5 mm in thickness, desiccated, with skin, fascia and marrow removed, provided by the Medical Education and Anatomical Services at the University of California San Diego). The acoustic intensity was controlled by changing the activation voltage. We calculated safety indices (spatial peak pulse average intensity, spatial peak temporal average intensity, mechanical index and thermal indices) and compared them with the maximum levels recommended by the Food and Drug Administration²⁷.

Volumetric ultrafast power Doppler imaging

The protocol consisted of two steps: ultrafast signal acquisition and post-processing. For signal acquisition, we used different time-delay profiles to transmit the diverging waves from five virtual sources that were 22.30 mm behind the device to obtain a view angle of 40° (Fig. 2a). We used three cycles of tone burst centred at 2 MHz with a

pulse repetition frequency of 3,000 Hz to activate the transducers. A group of five diverging waves was transmitted and received repeatedly 600 times within 1 s (Fig. 2a). The digitization rate of the received analog signals was 7.8125 MHz.

For post-processing, volumetric beamforming was performed on the raw radiofrequency data from each transducer 3,000 times. The beamformed data with different diverging waves were coherently compounded to form 600 frames of images. We implemented spatiotemporal clutter filtering (for example, singular value decomposition in this work) to separate blood flow (incoherent motion within the volume) from tissue motion (coherent motion within the volume) (Supplementary Discussion 9). After filtering, the energy of the temporal signal was integrated over the whole imaging block to calculate the power Doppler intensity in 3D (Fig. 2a). The computational load is inversely proportional to the size of each reconstructing voxel in the target region. We used a $0.77 \times 0.77 \times 0.77 \text{ mm}^3$ voxel, which corresponds to one wavelength of the ultrasound at 2 MHz in soft tissues, to maintain adequate spatial resolution and reasonable computational load.

To characterize the performance of this protocol, we conducted a test by using a Doppler flow phantom (ATS 523A, CIRS). We pumped Doppler fluid (769DF, CIRS) through the phantom with an internal diameter of 4 mm, positioned at an approximate depth of 60–80 mm. The volumetric flow imaging result (Supplementary Fig. 59) shows the flow profile of the phantom and is highly consistent with the ground truth collected by a conventional TCD probe (P4_2v, Verasonics).

Volumetric imaging by diverging waves is data and computation intensive. The raw radiofrequency data obtained within 1 s were approximately 800 MB. On beamforming and coherent compounding, the in-phase and quadrature data were inflated to approximately 4 GB. Subsequent processing steps, including singular value decomposition filtering, effectively reduced the final volumetric result to a more manageable size of around 5 MB. The data processing was executed within 10 min using a MacBook Pro equipped with an M1 Max chip, a 32-core graphical processing unit, and 64 GB of unified memory.

Automatic tracking of blood flow envelope

We first applied histogram equalization to enhance the contrast between the blood flow spectra and background noise, which improved the accuracy of envelope tracking (Extended Data Fig. 4). After that, we defined a step function to fit the spectra at each moment, which had a value of 1 in the frequency band lower than f_{step} (the envelope to be extracted), and 0 in the frequency band higher than f_{step} (Extended Data Fig. 4). The sum of the absolute differences at all frequencies between the spectra and the step function was defined as the error to quantify the fitting. We swept the frequency f_{step} from the lower (0 Hz) to the higher frequency (2,850 Hz) boundaries of the spectra and obtained the corresponding error values (Extended Data Fig. 4). The f_{step} value corresponding to the smallest error was the extracted envelope at this moment (Extended Data Fig. 4).

Study design for device validation

This study compared the cerebral blood flow measurements from the conformal ultrasound patch and a conventional TCD probe (P4_2v, Verasonics) to validate the agreement and correlation of their measurements at multiple arterial segments (that is, ACA, MCA M2, MCA M1, PCA, ophthalmic arteries, ICA, ICA siphon, TICA, basal artery and vertebral arteries). All studies on human participants in this work were approved by the Institutional Review Board at the University of California, San Diego (IRB #805201). The study was registered on ClinicalTrials.gov (NCT06073145). The inclusion criteria specified that the participants must be older than 18 years and in generally good health, without any severe medical conditions. The eligibility for the study was determined through a conversational screening process. Thirty-six participants in a random series were recruited and informed

of the potential risks and experimental procedures. Written consent forms were obtained before the test. The results had a statistical power of 83.07% to detect a difference of 5 cm s^{-1} on blood flow velocities, assuming a s.d. of 10 cm s^{-1} using a paired t -test with a 0.05 two-sided significance level. This statistical power is larger than the general statistical power requirement (that is, 80%) for clinical trials^{51,52}.

S. Zhou conducted all measurements throughout the study. We have taken several steps to ensure the accuracy and reliability of the measurements. First, S. Zhou completed online courses from The Institute for Advanced Medical Education about TCD (<https://www.iame.com/online-courses/vascular/transcranial-doppler-TCD-CME>) before conducting the tests. Second, this student received several hands-on training sessions from A. Lam, a clinically qualified ultrasonographer with more than 30 years of experience in TCD, before performing the measurements. Third, the student strictly adhered to the guidance^{24,53} to ensure the accuracy of the measurements during the testing process. Finally, D.W. Newell, another clinically qualified TCD ultrasonographer, provided guidance and supervision during the testing process and reviewed the results after the measurements, further ensuring the accuracy and reliability of the reference measurements. To illustrate the validity of the measurements made by S. Zhou, we compared the blood flow spectra obtained from A. Lam and S. Zhou by using a conventional TCD probe (Supplementary Fig. 60).

All procedures were conducted in accordance with the TCD examination guidelines^{24,53}. The participants were instructed to sit comfortably in a chair. The soft ultrasound patch and conventional rigid TCD probe were performed randomly in sequence for each participant. The ultrasound patch or a conventional TCD probe was placed on the temporal, orbital, submandibular and suboccipital windows to monitor different arterial segments. The temporal window can be further divided into anterior, middle and posterior windows¹ (Supplementary Fig. 13). The temporal window that provided the best cerebral signal in the TCD examination was selected for each participant.

The procedure for adhering the patch to the skin was as follows. First, we applied a layer of ultrasound gel to the surface of the target area. Next, we positioned the patch on the designated testing spot, ensuring the even distribution of the gel without any overflow onto the device surface. Finally, we secured the patch on the testing spot using Tegaderm (1626W, 3 M). This method ensured a stable adhesion between the patch and the skin, allowing for robust data acquisition. Diverging waves were used to reconstruct the volumetric power Doppler image, which facilitated the identification of various cerebral arteries. We then used focused waves to continuously monitor the blood flow spectra at target arterial segments.

We used a fast 3 s sweep speed that allowed a detailed examination of the spectra. A higher pulse repetition frequency led to higher measurement limits of Doppler shift (that is, a wider range of blood flow velocities) and also increased the ultrasound energy exposure. To balance the measurement limits and safety concerns, we chose a pulse repetition frequency of 2,500–4,000 Hz. The zero Doppler shift line (that is, baseline) was placed near the top or bottom of the screen to avoid aliasing (Supplementary Fig. 61). In the case of weak velocity signals, we increased the gain with a slow sweeping speed to visualize the Doppler shifts in the spectra. We lowered the power output of the devices, with a derated spatial peak temporal average intensity of $I_{\text{SPTA},3} < 17 \text{ mW cm}^{-2}$ (Food and Drug Administration Track 1 maximum recommended value for ophthalmic scans) to insonate through the orbital window to reduce ultrasound exposure of the eye²⁷.

Adhering to the ALARA (as low as reasonably achievable) principle²⁷ for general ultrasound diagnosis, we reduced the mechanical index and thermal index to limit the ultrasound exposure level during monitoring (Extended Data Fig. 6).

After identifying and optimizing the spectra of each arterial segment, we continued the recordings for 30 s. The time interval for switching between the patch and the TCD probe was approximately

5 min. In our study design, we anticipated generating 360 comparative sets of blood flow spectral measurements from 36 participants. However, owing to anatomical variations, some arterial segments were inaccessible, resulting in the acquisition of 254 comparative datasets. For each dataset, we conducted three repeated measurements, yielding a total of 762 individual data points for analysis. We calculated the average of peak systolic velocity, mean flow velocity, end diastolic velocity, pulsatility index and resistive index based on the recorded spectra for those 254 arterial segments. The measurements were concluded once 30 s spectral data of all arterial segments were recorded by both modalities three times. Data agreement was evaluated by Bland–Altman analysis (Fig. 3d–f and Supplementary Fig. 52). Data correlation was evaluated by scatter plots (Supplementary Figs. 52 and 53). No adverse events were reported throughout the duration of the examination.

Protocol for monitoring cerebral haemodynamics

To establish the baseline, the participants sat comfortably in a chair. The conformal ultrasound patch was attached to the temporal window. Flow spectra were monitored with focused beams on target arterial segments.

Hand grip. The protocol consisted of 40 s of resting, followed by 3 min of handgrip and subsequently 80 s of recovery (Supplementary Fig. 55). During the handgrip, the participants held a handgrip exerciser and exerted 30% of their maximum contraction force continuously. Switching of the test phases was signalled with cue tones.

Valsalva manoeuvre. The protocol started with a 20-s baseline recording. Following this, the participants inhaled deeply for 5 s (phase I), held their breath for 15 s (phases IIa and IIb), exhaled fully for 2.5 s (phase III) and finally breathed normally (phase IV) (Supplementary Fig. 55).

Word generation. After 15 s of baseline recording, the participants were first signalled by a cue tone for 3 s, given a letter visually for 2.5 s after a 2-s rest, and then asked to silently generate as many words as possible starting with this letter within 15 s and to orally report the words within 2.5 s (Supplementary Fig. 55).

Visual stimulation. A news magazine with emotionally neutral text was used. The protocol consisted of 20 s of baseline recording, 20 s of eye closing and 40 s of eye opening and reading silently (Supplementary Fig. 55). Changes between phases were signalled with cue tones.

To minimize the interference of confounding factors, each activity was performed 15 times on six participants. The interval between each test was more than 10 min or until the recorded values had returned to the baseline. The mean flow velocity was obtained from the recorded spectra and was expressed as mean \pm s.d.

Long-term monitoring. The participant was instructed to lie supine on a bed and remain as still as possible throughout the monitoring session. This positioning ensured that the patch was not in direct contact with the pillow and that the head was not pressing on the patch. The ultrasound patch was securely affixed to the participant's temporal window by Tegaderm (1626W, 3 M) for volumetric imaging. The MCA position was then located and targeted by a focused ultrasound beam. We placed a wearable gyroscope in close proximity to the ultrasound patch. This enabled us to correlate head movements with any changes in signal quality. The recording was conducted without interruption for 4 h until the device was powered off.

TCD sonography	Schematics	Results
1D	 <p>Conventional TCD probe (Multigon® TOC1M)</p>	 <p>Power M-mode</p>
2D	 <p>Conventional TCD probe (P4_2V)</p>	 <p>Duplex mode</p>
3D	 <p>Conformal ultrasound patch</p>	 <p>Power Doppler mode</p>

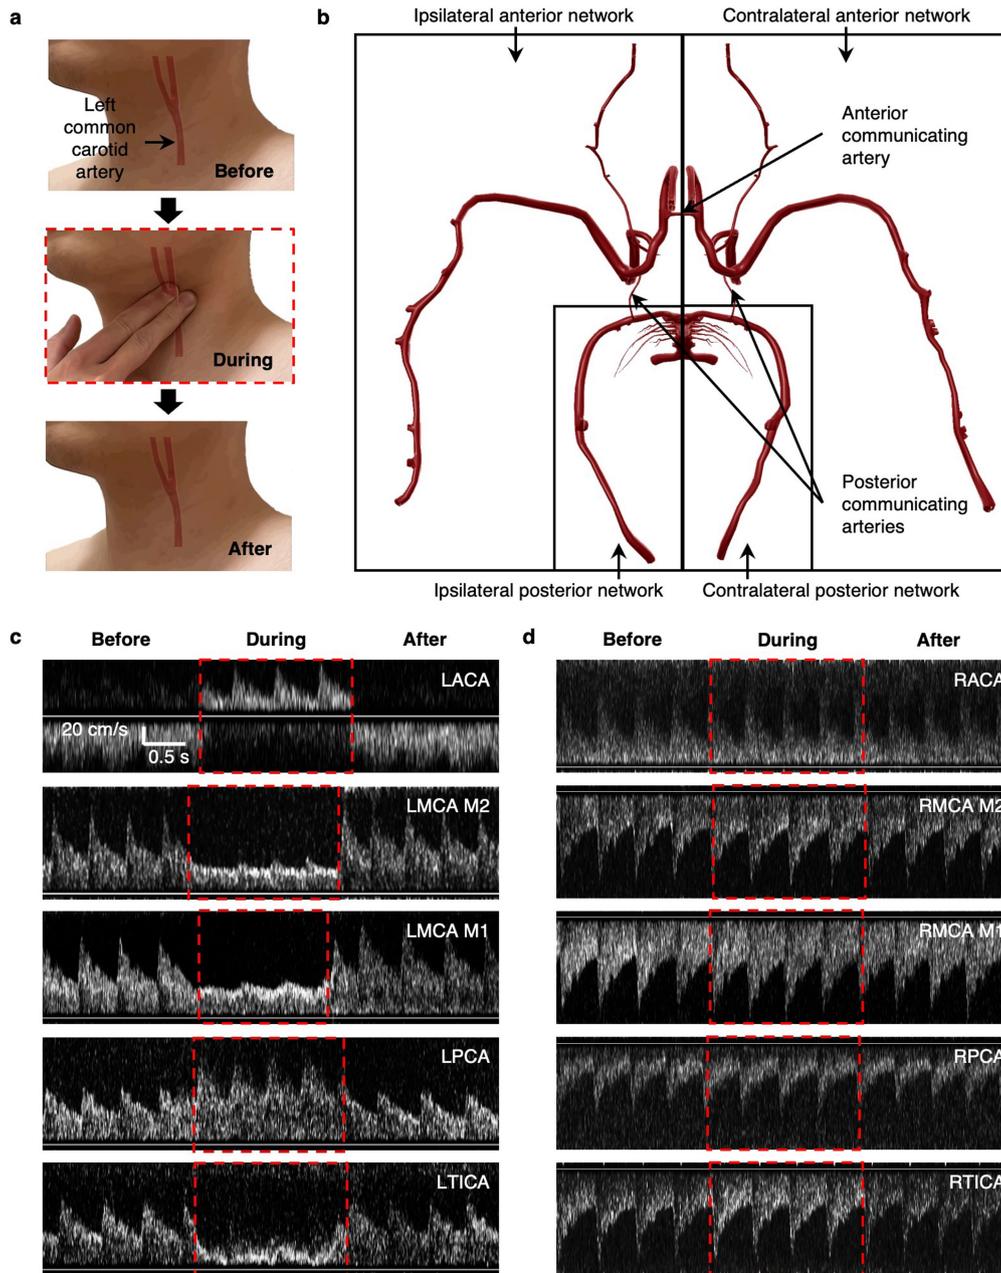

Extended Data Fig. 1 | 1D, 2D, and 3D TCD sonography. TCD sonography can be performed in different modes. The conventional TCD probe with a single transducer insonates target arteries in 1D, and the power M-mode results show collected blood flow signals⁵⁵. The conventional phased array probe with a linear transducer array insonates target arteries in two dimensions. The acquired duplex mode (that is, combined B-mode and color Doppler mode) results show the collected tissue signals and blood flow directions in the plane (<https://www.medison.ru/ultrasound/gal641.htm>). The conformal ultrasound patch with a matrix array insonates the target arteries in 3D, and the power

Doppler mode results show the collected volumetric blood flow signals. A much larger computation power will be needed to reconstruct volumetric duplex mode images. Because we only consider the morphology of the vasculature rather than the surrounding tissues and blood flow directions, we focus on the power Doppler mode in this study. Note that conventional probes require handholding, which is impractical for long-term monitoring and generates results that are operator-dependent. The conformal ultrasound patch is self-adherent and overcomes these two challenges.

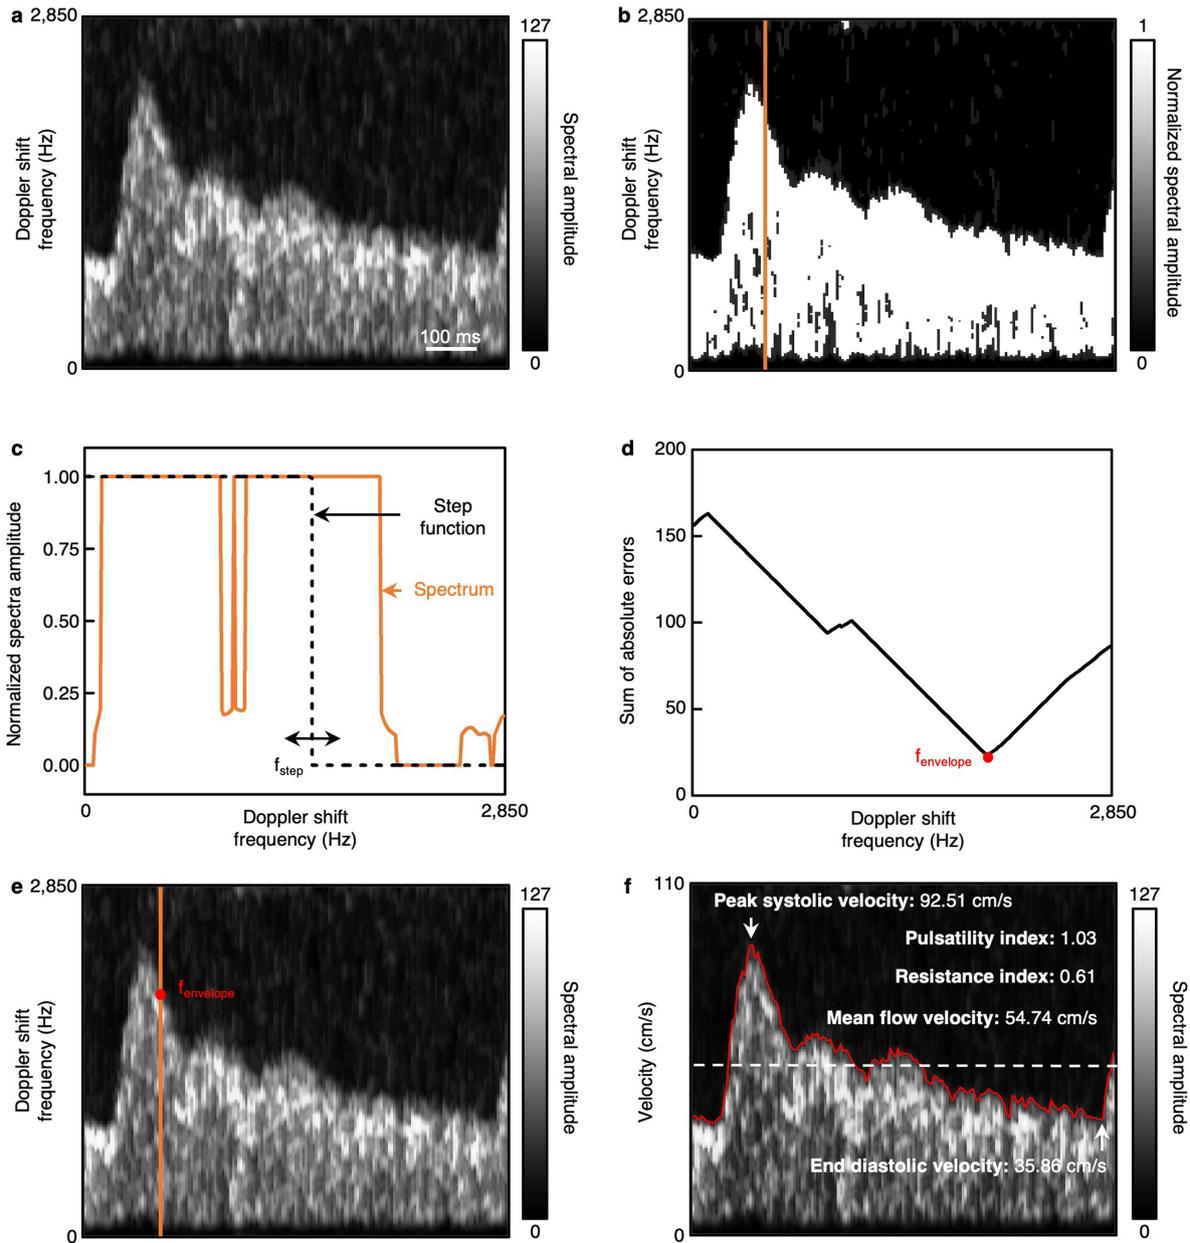

Extended Data Fig. 2 | Ultrasound exposure safety. **a**, System set-up for characterizing ultrasound exposure safety. The hydrophone is controlled by a 3D linear motor in a water tank. A formalin-fixed human skull sample is used to evaluate skull induced attenuation. **b**, Ultrasound intensity measured by the hydrophone. The maximum derated intensities of both diverging and focused

beamforming strategies before derating are set to around 370 mW cm^{-2} . The average intensity loss of the ultrasound beams after skull penetration is around 83% for both beamforming strategies. All of the measured results are lower than the maximum level recommended by the Food and Drug Administration (that is, 720 mW cm^{-2})²⁷.

Extended Data Fig. 3 | Blood flow spectra of compressing the left common carotid artery. **a**, Schematics of before, during, and after the compression test. **b**, The circle of Willis can be divided into four parts, including ipsilateral anterior, contralateral anterior, ipsilateral posterior, and contralateral posterior networks. These four parts are connected by one anterior communicating artery and two posterior communicating arteries⁴⁸. **c**, The blood flow spectra of ACA, MCA

M2, MCA M1, PCA, and TICA segments on the left side before, during, and after the compression test. The red dashed boxes label the period during the compression. **d**, The blood flow spectra of ACA, MCA M2, MCA M1, PCA, and TICA segments on the right side before, during, and after the compression test. The red dashed boxes label the period during the compression. The spectra share the same scale bars.

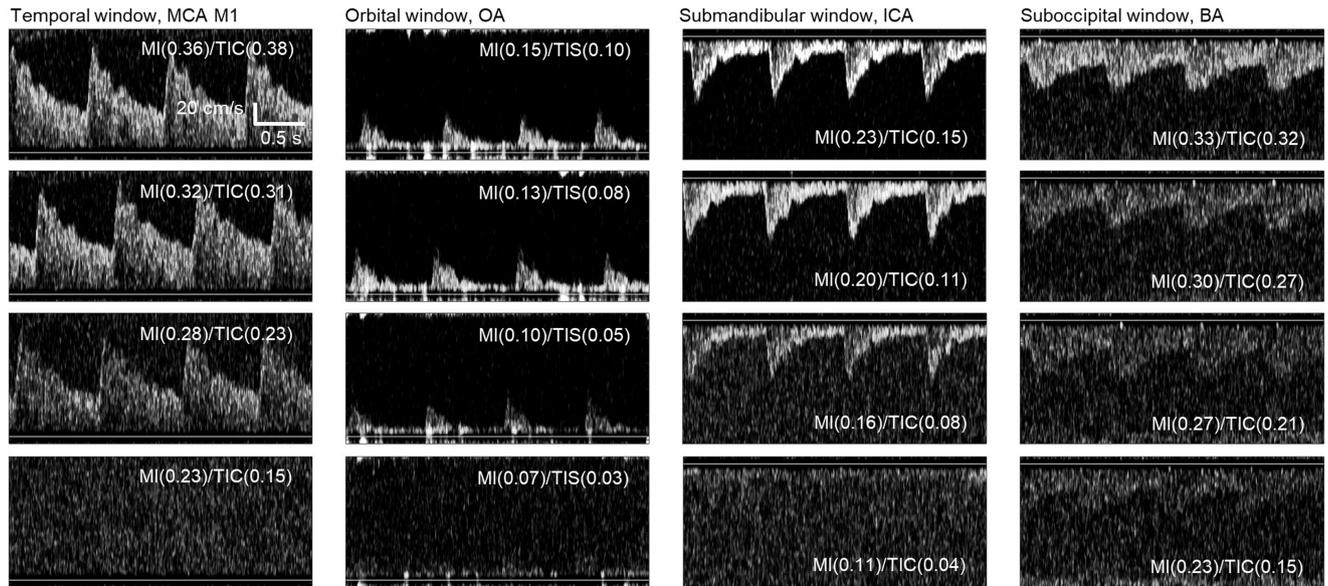

Extended Data Fig. 4 | Autonomous envelope tracking and parameter calculation. **a**, Spectrum Doppler of blood flow in one cardiac cycle. **b**, The spectrum Doppler is normalized first. After that, the spectrum with an amplitude higher than 0.2 is set 1, while the spectrum with an amplitude lower than 0.1 is set 0. This enhances the contrast between spectrum Doppler and noise. **c**, The orange curve is the amplitude snapshot of the enhanced spectrum in **b**, as labelled by the orange line. The enhanced spectrum has a similar shape like a step function. Therefore, we fit the spectrum using a step function to extract the envelope. The dashed black curve is one example of a step function.

Changing f_{step} will form different step functions. **d**, To find the step function that fits the spectrum the best, the sum of absolute errors is defined to quantify the difference between the spectrum curve and the step function. f_{step} sweeps from 0 to 2,850 Hz. The f_{step} corresponding to the minimum sum of absolute errors is the desired $f_{envelope}$. **e**, $f_{envelope}$ is the envelope corresponding to the spectrum at one moment. **f**, The entire envelope is extracted using the above method and labelled by a red line. The peak systolic velocity, mean flow velocity, end diastolic velocity, pulsatility index, and resistance index are calculated based on the tracked envelope. The spectra share the same timescale bar.

Extended Data Fig. 5 | Optical images of using different devices for TCD sonography. **a**, Optical images of a participant during and after using the conventional TCD probe for 30 min. The pressing results in discomfort and redness patterns on the skin. **b**, Optical images of the participant during and after using a conventional TCD headset for 30 min. The screwing and pressing result in discomfort and redness patterns on the skin. **c**, Optical images of the participant during and after using a customized TCD headset for 30 min. This

headset is designed for monitoring cerebral blood flow during brain procedures. The screwing and pressing result in discomfort and redness patterns on the skin. **d**, Optical images of the participant during and after using the conformal ultrasound patch for 30 min. This mechanical design eliminates the need for uncomfortable pressure and substantially reduces skin irritation. The images share the same scale bar. The inset images share the same scale bar.

Extended Data Fig. 6 | Doppler spectra acquired from all transcranial windows by using different mechanical indices and thermal indices. As the mechanical index and thermal index decrease, the signal quality correspondingly declines. The optimal mechanical indices and thermal indices were chosen to be as low as reasonably achievable during blood flow monitoring, balancing safety and signal quality. For the temporal and suboccipital windows, the optimal mechanical index and thermal index were around 0.3; for the orbital

window, we selected mechanical index around 0.13 and thermal index around 0.08; and for the submandibular window, the ideal mechanical index and thermal index were approximately 0.2 and 0.11, respectively. Importantly, these thresholds could be subject to individual variations due to physiological and anatomical differences. The spectra share the same scale bars. MI, mechanical index. TIC, cranium thermal index. TIS, soft tissue thermal index.

Extended Data Table 1 | Comparison of different techniques for cerebral blood flow monitoring

Method	Techniques	Invasiveness	Continuous	Absolute / Relative	Wearable	References
Nuclear medicine	Positron emission tomography	Yes	No	Absolute	No	⁵⁶
	Intra-arterial injection of ¹³³ Xe and ⁸⁵ Kr	Yes	No	Absolute	No	⁵⁷
	Single-photon emission computed tomography	Yes	No	Relative	No	⁵⁸
X-ray	Xe-enhanced computed tomography	No	No	Absolute	No	⁵⁹
	Perfusion computed tomography	Yes	No	Absolute	No	⁶⁰
	Digital subtraction angiography	Yes	No	Absolute	No	⁶¹
Magnetic resonance imaging	Dynamic susceptibility contrast magnetic resonance imaging	Yes	No	Absolute	No	⁶²
	Arterial spin labeling	No	Yes	Absolute	No	⁶³
Intravascular measurements	Nitrous oxide inhalation	Yes	No	Absolute	No	⁶⁴
Thermal probes	Jugular thermodilution	Yes	No	Absolute	No	⁶⁵
	Thermal diffusion flowmetry	Yes	Yes	Absolute	Yes	⁶⁶
Electrical probes	Electrical impedance tomography	No	Yes	Relative	Yes	^{8,67}
	Electroencephalography	No	Yes	Relative	Yes	⁷
Optical probes	Laser Doppler flowmetry	Yes	Yes	Absolute	Yes	⁶⁸
	Diffuse correlation spectroscopy	No	Yes	Relative	Yes	⁶⁹
	Near-infrared spectroscopy	No	Yes	Absolute	Yes	⁷⁰
Ultrasonography	Transit-time ultrasound flowmetry	Yes	Yes	Absolute	No	⁷¹
	Transcranial Doppler	No	Yes	Absolute	Yes	⁷²

Invasiveness, continuous monitoring, absolute or relative quantification, and wearability of the different techniques are compared. These parameters allow for analysing the advantages and disadvantages of current techniques to guide the design of the conformal ultrasound patch. References 7,8,56–72.

Extended Data Table 2 | Exemplary large group studies on TCD success rates

Number of Participants	Sex (Female percentage)	Acoustic Intensity (mW/cm ²)	Age (mean ± standard deviation) (years)	Race / Ethnicity	Success Rate (percentage)	Reference
2,735	56.7%	N/A	71.5±6.6	N/A	75% (A; D)	73
749	52.2%	N/A	<60 (n = 375); 60-79 (n = 230); ≥80 (n = 144)	Hispanic–Mestizo	94.9%; 70.4%; 56.3% (O; D)	74
705	41.8%	N/A	67.7±11.9	Mostly Asian	75% (A; D)	75
624	39.7%	550	55.2±16.1	N/A	92.8% (O; N/A)	76
597	24.5%	100	<40 (n = 43); 40-69 (n = 384); ≥70 (n = 170)	Mostly Asian	77.1% (N/A; D)	77
396	64.7%	N/A	62.6±6.0	Mostly Asian	72.2% (A; D)	78
376	35.9%	N/A	68.4±12.1	Asian	83.5% (A; D)	79
355	38.6%	N/A	64.5±13.2	Mostly Asian	71.2% (O; D)	80
262	48.9%	N/A	66±N/A	White (n = 202); Black or African American/Asian (n = 60)	79.8% (A; D)	81
239	46.9%	532; 456; 380; 304; 228; 152; 76	20-49 (n = 34); 50-69 (n = 115); 70-89 (n = 90)	Asian	71.5%; 61.5%; 59.8%; 59.4%; 53.6%; 48.1%; 38.1% (N/A, D)	82
182	40.1%	147~200	61.2±14.2	Mostly White	82% (A; S)	83
140	61.0%	N/A	74.1±6.6	Amerindians (n = 70) European ancestry (n = 70)	60% (O; D)	84
92	38.0%	N/A	64.0±9.5	Mostly Asian	65.8% (A; D)	85
90	51.1%	100	57.1±11.7	White (n = 66); Black (n = 19); Hispanic (n = 5)	88.9% (A; D)	86
36	47.2%	100~370	52.92±18.74	White (n = 15); Asian (n = 13); Black (n = 5); Hispanic/Latino (n = 3)	75.3% for conventional rigid probe; 70.6% for our patch (A; D)	This study

A, adequate signal, including optimal and suboptimal signals (for example, only part of the arterial segments cannot be accessed); D, double sides of the temporal window; N/A, not available; O, optimal signal; S, single side of the temporal window. This table summarizes findings from various studies on the success rate of the TCD examination across different demographic groups and applied acoustic intensities. Each study is categorized by the number of participants, sex distribution, applied acoustic intensity, age distribution, race/ethnicity of the study population, and the reported success rate. The last row presents aggregated data from this study, highlighting the similar success rates of this study to the published ones. References 73–86.

118 **Supplementary Discussion 1: Comparison of different methods for cerebral blood flow**
119 **monitoring**

120 Various techniques have been used to measure cerebral blood flow, including nuclear medicine,
121 X-ray, magnetic resonance imaging, intravascular measurements, thermal probes, electrical probes,
122 optical probes, and ultrasonography (Extended Data Table 1)¹⁻³.

123
124 (1) Nuclear medicine: The basic principle of nuclear medicine is to inject radiotracers and detect
125 their spatial and temporal kinetics in the cerebral vessels with radiation detectors. There are three
126 techniques: positron emission tomography, intra-arterial injection of ¹³³Xe and ⁸⁵Kr, and single-
127 photon emission computed tomography.

128
129 Positron emission tomography injects positron-emitting radiotracers (e.g., ¹⁵O) and measures its
130 concentration in the blood vessel with a positron emission tomography scanner⁴. By taking
131 advantage of the 2 min short half-life of the radiotracer, cerebral blood flow can be calculated from
132 the dynamics of tracer delivery through the arteries². There is minimal tissue diffusion due to the
133 short half-life of the radiotracers. Therefore, this method is accurate in quantitatively analyzing
134 absolute cerebral blood flow, but the bulky and expensive scanner limits its widespread use, and
135 continuous monitoring for an extended period of time is not possible due to the short half-life of
136 the radiotracer.

137
138 The intra-arterial injection of ¹³³Xe and ⁸⁵Kr radiotracers is mainly performed with scintillation
139 detectors⁵. These detectors can monitor γ -ray and β particle emissions, which are caused by the
140 exponential decay over time of ¹³³Xe and ⁸⁵Kr, respectively. Quantitative cerebral blood flow can
141 be derived from the radioisotope clearance curve. Therefore, each injection of radiotracers can
142 only provide one cerebral blood flow measurement, and a new measurement can only be performed
143 after ensuring the previously injected radiotracers have fully decayed².

144
145 Single-photon emission computed tomography administers radiotracer compounds composed of a
146 radioactive isotope (e.g., ^{99m}Tc or ¹²³I) coupled with a biologically active ligand (e.g.,
147 hexamethylpropyleneamine oxime or ethyl cysteinate dimer)⁶. The biological carrier enables the
148 radioactive isotope to pass through the blood-brain barrier and subsequently metabolize
149 intracellularly in the brain tissue². Compared to positron emission tomography, which measures
150 the positron emission of the radiotracers, here the emitted lower energy γ -rays from the radiotracers
151 are detected in single-photon emission computed tomography. The multi-headed gamma camera
152 with collimators detects the γ decay of the radiotracers and reconstructs the spatial distribution in
153 three dimensions (3D). By observing the γ decay over time, relative cerebral blood flow can be
154 detected. This technique can only be performed in controlled clinical settings because of the
155 injection of the radiotracers and the setup of bulky collimator machines.

156
157 (2) X-ray: X-ray techniques, including xenon-enhanced computed tomography, perfusion
158 computed tomography, and digital subtraction angiography, track substances using computed
159 tomography scanners.

160
161 Xe contrast-enhanced computed tomography takes advantage of the rapid diffusion mechanism of
162 Xe in the brain. Xe is administrated by inhalation, and the computed tomography image can
163 determine the cerebral blood flow based on the concentration difference of Xe diffusing through

164 the brain tissue and baseline measurement without Xe inhalation². Any computed tomography
165 scanner can be used for Xe contrast-enhanced applications. The concentration of Xe is critical in
166 performing safe but reliable measurements; thus, continuous monitoring is limited by the diffusion
167 of Xe, and the associated equipment cannot be miniaturized into wearables⁷.

168
169 Perfusion computed tomography injects iodinated contrast agent into cerebral vessels and
170 measures its relative concentration over time, which is proportional to the change in image signals
171 in x-ray images⁸. Thus, perfusion computed tomography selects the region of interest to measure
172 the blood volume, and high frame rate data are acquired to measure blood flow mean transit time².
173 This technique involves invasive injection and data are non-continuous. Also, the quantification
174 of cerebral blood flow has not been validated clinically. The accuracy varies significantly among
175 different arteries.

176
177 Digital subtraction angiography also injects iodinated contrast agent into cerebral vessels. An
178 initial contrast-free image is taken prior to the injection. Then this image is subtracted from the
179 images during contrast agent injection digitally⁹. This technique, therefore, has high temporal
180 information, which can provide cerebral blood flow measurements¹⁰.

181
182 (3) Magnetic resonance imaging: Magnetic resonance imaging produces high-quality 3D
183 anatomical images with high magnetic fields of a large scanner, making it impractical to achieve
184 a wearable format. This method includes dynamic susceptibility contrast magnetic resonance
185 imaging and arterial spin labeling.

186
187 Dynamic susceptibility contrast magnetic resonance imaging administers Gd-based paramagnetic
188 contrast agents and measures the transient decrease in brain signal intensities. This signal intensity
189 approximates the contrast agent concentration, which can be quantitatively converted into cerebral
190 blood volume. The technique is based on the difference in magnetic susceptibility of the contrast
191 agent in intravascular and extravascular regions¹¹. The conversion requires the injected
192 concentration and transient signal loss during the contrast agent movement through the blood
193 vessels, so continuous monitoring is not possible. Because this technology is a recent development,
194 standardized protocols are not available for wide use in clinics².

195
196 Arterial spin labeling relies on the magnetically labeled arterial blood water protons². Continuous
197 and quantitative analysis is achieved by the radiofrequency pulses that invert the magnetization
198 direction of the blood water protons, allowing local cerebral blood flow to be quantified by the
199 amount of negative magnetization in one of the cerebral arteries¹².

200
201 (4) Intravascular measurements: Intravascular measurements require the injection of tracers to
202 measure the blood flow changes after their circulation through the cerebral blood vessels. There
203 are two methods: nitrous oxide inhalation and jugular thermodilution. Jugular thermodilution
204 measures the temperature differences after tracer injection, and thus is discussed in thermal probes
205 section.

206
207 Nitrous oxide is a freely diffusible tracer. The concentration of nitrous oxide is measured at the
208 femoral arterial and the jugular venous sites to find the time it takes for the concentration to reach
209 a steady state (i.e., the time for the concentrations of nitrous oxide at the femoral arterial site and

210 the jugular venous site to be the same). The time required to reach this steady state is used to
211 calculate the cerebral blood flow¹³. Then, the diffusion dynamics of nitrous oxide can be correlated
212 with systemic cerebral blood flow. Only one measurement of cerebral blood flow can be
213 quantitatively obtained. The inhalation of nitrous oxide limits its use for continuous monitoring².
214 In addition, due to the catheterization of the femoral artery or the jugular vein, this technique is
215 cumbersome and invasive, which is not suitable for long-term use.

216
217 (5) Thermal probes: Thermal probes use thermistors to measure the temperature change during
218 thermal intervention to the cerebral blood flow. There are two techniques: jugular thermodilution
219 and thermal diffusion flowmetry.

220
221 The jugular thermodilution method uses a catheter to inject a cold fluid that is miscible in blood
222 into the internal jugular vein to generate a thermal perturbation². Then, the temperature differences
223 can be measured by the thermistors attached to the inner and outer walls of the catheter and further
224 converted into a measurement of cerebral blood flow. The straightforward calculation provides a
225 quantitative real-time continuous assessment of overall cerebral blood flow¹⁴. Nevertheless, this
226 technique is invasive and patients' tolerance to the cold fluid severely limits the duration of the
227 test.

228
229 Thermal diffusion flowmetry is based on heat transfer of biological tissues: conductive properties
230 of the brain tissues and cerebral blood flow². The reference thermistor measures the normal brain
231 temperature while the active thermistor measures the heated site. Because thermal power is
232 dissipated via heat transfer and the conductive properties of the brain tissues are assumed to be
233 constant, the temperature changes are related to the convective effects of the cerebral blood flow¹⁵.
234 This method can provide measurements of absolute local cerebral blood flow continuously.
235 However, because of its invasiveness, thermal diffusion flowmetry is usually done on critically ill
236 patients.

237
238 (6) Electrical probes: Electrical probes extract data from changes in conductivity, impedance, or
239 potentials from tissues and cells. Electrical impedance tomography and electroencephalography
240 methods measure these electrical signals from the brain to calculate cerebral blood flow.

241
242 Electrical impedance tomography utilizes the impedance differences between blood and the brain
243 tissue³. Blood has a lower impedance than the brain tissue. Thus, as the blood flow increases in a
244 certain region, its impedance decreases. These relative impedance changes in cerebral blood flow
245 can be detected by applying a weak excitation current to the region of interest to create a potential
246 field; then, an array of electrodes measures the potential changes from the known applied current¹⁶.
247 Those electrodes can be engineered into a wearable format. However, because of the fringe effect
248 of the electric field (i.e., the non-uniform electric fields around the edge of the electrodes), the
249 signal-to-noise ratio is intrinsically low, resulting in limited spatial resolution of imaging areas of
250 interest and blood flow measurement from individual vessels¹⁷.

251
252 Electroencephalography detects the voltage differences stemming from the activities of neurons¹⁸.
253 Oscillations of certain frequencies in the electroencephalography signals represent different brain
254 functions, and they have a close relationship with cerebral blood flow¹. In other words, changes in
255 cerebral blood flow cause different oscillation frequencies. Electroencephalography is measured

256 noninvasively with scalp electrodes; thus, wearable continuous analysis is possible. However, due
257 to the indirect calculation of cerebral blood flow, the data interpretation is subjective and the
258 measurement accuracy is questionable.

259
260 (7) Optical probes: Optical methods such as laser Doppler flowmetry, diffuse correlation
261 spectroscopy, and near-infrared spectroscopy are based on reflection, scattering, transmission, or
262 absorption of a light source due to tissue properties, which can be used to assess cerebral blood
263 flow.

264
265 Laser Doppler flowmetry utilizes the Doppler effect to measure the frequency shift caused by
266 moving red blood cells. A fiber-optic probe sends a monochromatic light to the targeted vessel,
267 and a photodetector measures the scattered light that has a Doppler-shifted frequency, which can
268 be converted into cerebral blood flow¹⁹. The major merit of this technique is that it can provide
269 highly localized detection, even down to the microcirculation. However, due to the limited
270 penetration depth of light, the probe needs to be inserted invasively into the brain tissue². In
271 addition, the low Young's modulus of the brain causes the probe to be easily displaced. Thus, there
272 is often signal loss, and a wearable format is not ideal.

273
274 Diffuse correlation spectroscopy detects cerebral blood flow by analyzing the scattering effect of
275 a light source noninvasively emitted from the skin surface². Near-infrared light can propagate
276 through the skull, brain tissues, and moving red blood cells in the cerebral vessels. The scattered
277 light from each depth in the brain is then measured from the skin surface and further analyzed to
278 determine relative changes in blood flow. Thus, this method can only measure the relative blood
279 flow index, the percent change relative to a baseline value. By increasing the source-detector
280 distance on the skin surface, signals from deeper areas can be monitored but with less sensitivity
281 due to decreased light intensity²⁰. Diffuse correlation spectroscopy can be miniaturized into a
282 wearable format.

283
284 Near-infrared spectroscopy is also a diffuse optical method but with two light sources of different
285 wavelengths to noninvasively probe the concentration of oxyhemoglobin and deoxyhemoglobin
286 in the cerebral cortex²¹. In the brain, the dynamic hemoglobin concentrations are the main
287 contributors to the changes in light absorption. Thus, the absorption is used to calculate the amount
288 of oxyhemoglobin and deoxyhemoglobin, and the absorption difference is highly correlated with
289 cerebral blood flow²². However, various factors such as blood flow, blood volume, capillary
290 density, and metabolic rate of oxygen may also affect hemoglobin concentration, limiting the
291 calculation accuracy.

292
293 (8) Ultrasonography: When ultrasound is backscattered or reflected from the blood vessels, the
294 received ultrasound waves contain blood flow information from inside the blood vessels. There
295 are two ultrasound techniques for monitoring cerebral blood flow: transit-time ultrasonic
296 flowmetry and transcranial Doppler ultrasound.

297
298 Transit-time ultrasonic flowmetry measures the time for the blood to flow from an ultrasound
299 transducer placed upstream to another ultrasound transducer placed downstream to a blood vessel²³.
300 This transit time is directly proportional to the volumetric blood flow. In principle, the device can
301 be wearable and continuous. However, because the major cerebral blood vessels are located deep

302 inside the brain, accurate assessments must be performed invasively by perivascularly placing the
303 transducers on the vessel wall, which limits applications of this method to only surgical settings².

304
305 The transcranial Doppler (TCD) ultrasound is also based on the Doppler effect, noninvasively
306 measuring the frequency shift between transmitted ultrasound waves and waves backscattered by
307 moving red blood cells²⁴. Thus, TCD can provide local assessment of individual vessels in the
308 cerebral arterial network². To achieve continuous monitoring, wearable TCD headsets have been
309 developed. However, these headsets typically require tight fixation to the head, which is too
310 uncomfortable to wear for >30 min. Also, due to the small cerebral vasculature, the signals can be
311 easily lost because slight movements of rigid ultrasound probes may shift the ultrasound beam
312 away from the vessels. There are some customized two-dimensional matrix arrays used to map the
313 volumetric cerebral vascular network. For example, a “wearable phased array” used an 8 by 8 array
314 with 1.6 mm by 1.6 mm element size²⁵. The pitch size (i.e., 1.7 mm) is much larger than the
315 ultrasound wavelength (i.e., 0.77 mm), resulting in significant grating lobes and limited spatial
316 resolutions for volumetric reconstruction. This system was used to target the middle cerebral artery
317 (MCA) and the signals from other cerebral arteries were ignored, which resulted in limited value
318 for clinical decision making. Another example is a “Volumetrics Medical Imaging (VMI, Durham,
319 NC) system” using a sparse two-dimensional array with 0.35 mm pitch size²⁶. Combined with
320 contrast agents, it could generate high spatial resolution volumetric reconstruction. However, this
321 system used a normal line-by-line scanning mode with a much lower temporal resolution, and its
322 bulky size is not suitable for continuous long-term monitoring.

323
324 **Supplementary Discussion 2: Acoustic beam attenuation by the skull**

325 Ultrasound is widely used to track Doppler signals of blood flow throughout the body. However,
326 compared to other vessels in the body, the cerebral vessels are challenging to be sensed by
327 ultrasound due to the skull-induced strong acoustic attenuation²⁷.

328
329 The skull is comprised of outer cortical bone and inner cancellous bone²⁸. The cortical bone is
330 mainly composed of osteon tissues with minimal porosity, and it has a much larger acoustic
331 impedance than that of soft tissues. On the other hand, the cancellous bone is also made of osteon
332 tissues but has anisotropic heterogeneous porous structures with 75-85% porosity²⁸. The pores are
333 filled with bone marrow, which has a similar acoustic impedance to that of soft tissues. Therefore,
334 the overall porous cancellous bone has a different acoustic impedance from that of soft tissues and
335 the cortical bone.

336
337 There are three major attenuation mechanisms when the ultrasound beam travels through the skull:
338 reflection, absorption, and scattering (Supplementary Fig. 2).

339
340 First, as the acoustic waves travel through an interface of two media of different acoustic
341 impedances, some of the wave energy gets transmitted through while some gets reflected from the
342 interface. Therefore, there are reflections at all interfaces including scalp soft tissue-cortical bone
343 interface, cortical bone-cancellous bone interface, and cortical bone-brain tissue interface. The
344 larger the impedance mismatch between the two media, the larger the reflection. The acoustic
345 impedance of soft tissues is around $1.66 \times 10^6 \text{ kgm}^{-2}\text{s}^{-1}$, while that of osteon tissues is approximate
346 $6.47 \times 10^6 \text{ kgm}^{-2}\text{s}^{-1}$, creating a substantial mismatch between them²⁹.

347

348 Second, absorption is the process when the ultrasound energy is converted into heat. This occurs
349 due to the mechanical nature of ultrasound waves. As the ultrasound waves pass through the tissues,
350 the compositional elements of the tissues longitudinally vibrate and pass the pressure wave to the
351 next tissue elements. The efficiency of ultrasound wave propagation through the tissue is related
352 to various factors of the tissue composition (e.g., material, density, and structural orientation).
353 Cortical bone exhibits higher attenuation coefficient (e.g., 1 to 10 dB·cm⁻¹MHz⁻¹)³⁰ than that of
354 soft tissues (e.g., 0.3 to 0.7 dB·cm⁻¹MHz⁻¹ for most soft tissues), Higher attenuation is often
355 associated with higher absorption and therefore higher temperature rise.

356
357 Third, as the ultrasound beam travels through a microstructure that is composed of various
358 materials, scattering occurs, especially when the materials have large differences in acoustic
359 impedances²⁹, causing the ultrasound beam to diverge in all directions. Consequently, in the skull,
360 the porous microstructures of the cancellous bone with large differences in acoustic impedance
361 between the osteon tissues and the bone marrow have substantial scattering effect. The scattering
362 effect is dependent on the ultrasound wavelength and the microstructure size³¹. If the
363 microstructures have sizes close to the ultrasound wavelength, the ultrasound waves will scatter
364 relatively anisotropically, but if the sizes are much smaller than the wavelength, then the
365 ultrasound waves will scatter less anisotropically. In general, longitudinal waves incident upon
366 trabeculae can scatter into both shear and longitudinal waves. The conversion of incident
367 longitudinal waves into scattered shear waves, followed by rapid absorption of scattered shear
368 waves, has been shown to be a significant source of attenuation in cancellous bone³¹. In addition,
369 the cancellous bone thickness is different in each person and the thickness is nonuniform across
370 different regions in the skull of the same person. Therefore, different people and skull regions will
371 cause different acoustic beam patterns³².

372
373 In all, the skull causes all three types of attenuation that substantially decrease the signal-to-noise
374 ratio of ultrasound probes. We have taken these factors into consideration when designing the
375 conformal ultrasound patch. Higher ultrasound frequencies can provide better image quality but
376 also stronger reflection, absorption, and scattering and thus smaller signal-to-noise ratio. Therefore,
377 to balance the spatial resolution and signal-to-noise ratio, the central frequency in this work is 2
378 MHz. In addition, transmitting the ultrasound waves with a longer pulse duration provides a much
379 smaller bandwidth, which leads to a higher sensitivity to Doppler shift. Temporal bone is selected
380 as an acoustic window of the skull owing to its small thickness compared to other parts of the skull.
381 The temporal window usually causes about 80% loss in ultrasound intensity. Therefore, a higher
382 acoustic intensity (around 60 to 370 mW/cm² spatial peak temporal average intensity) is utilized
383 to ensure sufficient acoustic energy to insonate the arteries through the skull, which gives a
384 sufficient signal-to-noise ratio to measure Doppler shifts of blood flow in the intracranial vessels.
385 All acoustic intensities used in this work are under the Food and Drug Administration maximum
386 recommended level for diagnostic ultrasound³³.

387
388 While we have made substantial efforts to mitigate signal attenuation caused by the skull, we must
389 acknowledge the persistence of certain inaccessible transcranial windows. These are typically due
390 to factors such as increased skull thickness, density, or the presence of numerous air-filled cavities,
391 all of which can significantly attenuate ultrasound waves. This, in turn, diminishes signal quality
392 and obstructs reliable cerebral blood flow measurements. Such hindrances represent an inevitable
393 limitation that is inherent to both conventional TCD probes and the conformable ultrasound patch.

394

395 **Supplementary Discussion 3: Phase aberration effect**

396 When using the conformal ultrasound patch for imaging, each transducer in the patch will emit
397 ultrasound waves with a specific time-delay profile. These ultrasound waves are backscattered and
398 reflected from the tissues and received by the transducer array for image reconstruction. Ideally,
399 we assume the speed of sound in tissues is constant, and the patch has no physical deformation
400 (i.e., all transducers are on the same flat plane). Then, to make all ultrasound waves arrive at a
401 target in coincidence, the time-delay profile can be calculated based on the geometric path length
402 between the target and each element in the array.

403

404 However, inhomogeneous media and irregular geometries of the transducer array will cause phase
405 aberration, which limits spatial resolution in ultrasound imaging (Supplementary Fig. 3)³⁴⁻³⁶. First,
406 the speed of sound in the body varies over a wide range. The speed of sound is very different
407 between soft tissues and the skull, by a factor of around 2. In addition, there is variation in shape,
408 thickness, and composition of the skull. Two locations on the same skull can experience substantial
409 differences in ultrasound propagation speed, which makes the phase aberration even worse in
410 transcranial studies. Second, the transducer array may have uncertain curvatures while the
411 ultrasound patch conforms to the scalp. The geometric irregularities induce as large errors in the
412 time-of-flight as several ultrasound wavelengths, which will lead to uncertain phase aberrations.

413

414 Low ultrasound frequencies can minimize such phase aberrations (Supplementary Fig. 3)³⁷. Lower
415 ultrasound frequencies have longer wavelengths, which lead to a smaller relative phase angle shift.
416 As a result, ultrasound waves with lower frequencies are distorted less and thus can reconstruct
417 better images than those with higher frequencies (Supplementary Fig. 3).

418

419 **Supplementary Discussion 4: Technology advancement of the conformal ultrasound patch**

420 Wearable ultrasound devices could sense signals in deep tissues³⁸; however, their applications
421 were drastically limited by the signal attenuation and phase aberration of the bone, which
422 constrains their usability to soft tissues. In this study, we demonstrate the first wearable ultrasound
423 device capable of deep tissue sensing through the bone. This capability is unprecedented and
424 overcomes a longstanding barrier in wearable ultrasound technology.

425

426 Moreover, existing wearable ultrasound devices are limited to providing one-dimensional
427 signals^{39,40}, two-dimensional images⁴¹⁻⁴⁴, or three-dimensional images by piecing multiple two-
428 dimensional slices together^{45,46}. The piecing approach introduces potential inaccuracies to the final
429 result. First, it relies on extrapolation from adjacent slices to create a complete three-dimensional
430 image, introducing errors from approximation. Second, these slices are acquired with typically
431 about 1 s time gaps. Considering the continuous movement of the tissue, these time gaps lead to
432 mismatch between slices. This study addresses this limitation by directly reconstructing three-
433 dimensional images, which drastically reduces the time needed for image reconstruction and
434 substantially enhances the image quality.

435

436 Overcoming each one of these two limitations necessitated extensive engineering innovation. This
437 study significantly enhances the capabilities of wearable ultrasound devices, bringing their
438 functionality in line with advanced ultrasound instruments used in clinical settings. This
439 technology supports a wide range of medical and research applications previously thought

440 impossible (Supplementary Discussion 16).

441

442 **Supplementary Discussion 5: Cerebral vascular network**

443 The cerebral vessels intertwine and form a complicated network (Fig. 3e). There are four principal
444 arteries that provide the blood supply to the brain, including the internal carotid artery (ICA) and
445 vertebral artery on each side⁴⁷. The ICA traverses through the base of the skull to provide the
446 anterior supply, while the vertebral artery runs through the spinal column in the neck and provides
447 the posterior supply (Fig. 3e)⁴⁸.

448

449 The terminal ICA (TICA), the end part of the ICA, gives off the middle cerebral artery (MCA),
450 anterior cerebral artery (ACA), and ophthalmic artery branches. The MCA extends laterally and
451 slightly anteriorly and carries around 80% of the blood flow to the brain (Fig. 3e)⁴⁸. It is one of the
452 most important cerebral arteries whose blood flow reflects the overall blood supply of the brain.
453 The ACA reaches out medially, then turns more anteriorly until it reaches to the brain midline (Fig.
454 3e)⁴⁸. The anterior communicating artery is a small segment joining each side of the ACA in the
455 brain midline (Extended Data Fig. 3)⁴⁸. The ophthalmic artery runs through the orbital cavity and
456 nasally towards the eye (Fig. 3e)⁴⁸. The combination of these arteries builds up the anterior
457 circulation network in the brain.

458

459 The vertebral artery from each side joins at the front of the brainstem in the midline to form the
460 basilar artery (Fig. 3e). The posterior cerebral artery (PCA) arises from the basilar artery and runs
461 laterally and curves posteriorly (Fig. 3e)⁴⁸. The vertebral artery, basilar artery, and PCA are the
462 major arteries for the posterior circulation network in the brain.

463

464 At the central cranial base, the anterior and posterior circulation are connected by the posterior
465 communicating arteries to form an anastomotic structure called the “circle of Willis” (Fig. 3e)⁴⁷.
466 The configuration of the cerebral arteries that form the circle of Willis is considered an engineered
467 redundancy for collateral circulation, theoretically allowing the brain to preserve sufficient blood
468 flow and perfusion to its contralateral aspect to avoid or limit injury in the event of focal cerebral
469 artery blockage or stenosis⁴⁹.

470

471 Compressing the left common carotid artery can help to validate this concept. If there were no
472 anterior communicating artery and posterior communicating arteries, compressing the left
473 common carotid artery would block the blood flow in the left ICA and therefore induce a shortage
474 of blood flow in ipsilateral anterior arterial segments (e.g., left TICA, left MCA, and left ACA).
475 However, owing to the presence of the anterior communicating artery that connects the LACA and
476 RACA, and posterior communicating arteries that connect the PCA and TICA, in healthy
477 participants, blood would flow from the contralateral (e.g., right TICA, right MCA, and right ACA)
478 and posterior (e.g., left and right PCA) networks into the ipsilateral anterior arteries to maintain
479 the supply (Fig. 2c-d and Extended Data Fig. 3). Blood flow changes in all these arterial segments
480 are important because all of them are needed to maintain appropriate blood supply in the brain
481 during the compression test.

482

483 Note that the functional compensation can be influenced by the anatomical variations of the circle
484 of Willis. For instance, the hypoplasia or aplasia of certain arteries, such as the anterior
485 communicating artery or posterior communicating arteries could affect the efficiency of this

486 compensatory response^{50,51}. Hypoplastic or aplastic arteries may have a reduced capacity to
487 provide sufficient blood flow for compensation during the carotid compression, which could
488 potentially put the brain at risk during instances of unilateral carotid obstruction. These anatomical
489 variations underscore the importance of individualized assessment of cerebral perfusion and
490 highlight the advantage of our ultrasound patch in providing a personalized and comprehensive
491 evaluation of cerebral hemodynamics.

492
493 To visualize the circle of Willis, we used the conformal ultrasound patch to monitor the blood flow
494 in major cerebral arteries including ICA, MCA, ACA, ophthalmic artery, vertebral artery, basilar
495 artery, and PCA.

496
497 There are two reasons why the anterior communicating artery and posterior communicating
498 arteries are not monitored in this work. First, the blood flow signals from the anterior
499 communicating artery and posterior communicating arteries are typically not captured by TCD on
500 healthy participants. Because the bilateral blood flow is balanced, the collateral circulation is
501 closed and there is no blood flow in these arteries⁴⁸. Second, the anterior communicating artery
502 and posterior communicating arteries are small (about 1 mm in diameter)^{52,53} and are difficult to
503 be detected by TCD. In addition, the posterior communicating arteries are almost perpendicular to
504 the ultrasound waves from the temporal window, which leads to extremely weak Doppler signals⁴⁸.

505
506 Other cerebral arteries are of less clinical interest and are not considered as targets for standard
507 TCD sonography. Those arteries include the anteromedial central arteries, superior cerebellar
508 artery, pontine arteries, anterior spinal artery, posterior spinal artery, posterior inferior cerebellar
509 artery, etc.

510
511 The cerebral venous anatomy includes the superficial medullary veins and the deep medullary
512 veins^{54,55}. The superficial medullary veins start from subcortical veins that supply blood to the pial
513 veins on the surface of the cortex⁵⁵. The pial veins converge the blood and drain into the cerebral
514 veins. Structurally, the pial veins have a circumferential smooth muscle layer to prevent them from
515 being easily compressed at high intracranial pressures⁵⁵. All other cerebral veins do not have
516 muscular layers so they can expand freely⁵⁵. Compared to the superficial medullary veins, the deep
517 medullary veins are more extensive, which are perpendicular to the lateral ventricles and consist
518 of venules in the white matter⁵⁶. These two venous systems are connected via transcerebral veins
519 that traverse through the entire cerebral parenchyma⁵⁶. Because of the lesser interest in
520 cerebrovenous disorders compared to arterial diseases, using TCD to diagnose cerebral venous
521 blood flow has not yet been systematically established⁵⁷.

522 523 **Supplementary Discussion 6: The rationale for choosing 16 by 16 matrix array**

524 The primary reason for choosing a 16 by 16 array with 256 elements was due to the maximum
525 number of elements supported by the Verasonics Vantage 256™ system. Furthermore, the
526 complexity associated with managing a higher number of elements and their interconnections was
527 another factor that influenced our decision to select the 16 by 16 configuration.

528
529 We acknowledge that the spatial resolution could be further improved by using a larger array, such
530 as a 32 by 32 configuration. However, to implement this, we may need to synchronize four Vantage
531 256™ systems⁵⁸, which would introduce additional challenges in both hardware and software.

532 Four Vantage 256TM systems can support 1024 transducers, which substantially increase the
533 computational load and lower the frame rate. Moreover, a refined design would be necessary to
534 manage the increased complexity of the interconnections, which could present further difficulties.

535
536 Regarding fundamental limitations in the manufacturing process, a commercial 1024-channel
537 probe (Vermon) in our group features a 32 by 32 array, including three blank columns to
538 accommodate the interconnections. Although there are no insurmountable barriers to producing
539 larger array sizes, our choice of the 256-element array was primarily driven by practical
540 considerations and the need to balance performance, complexity, and resource constraints.

541
542 **Supplementary Discussion 7: Safety characterization of the conformal ultrasound patch**
543 TCD sonography follows the safety guidelines of the Food and Drug Administration for diagnostic
544 ultrasound³³. The conformal ultrasound patch is a medical device that may expose the operator and
545 patient to various safety hazards. Therefore, the device must conform to relevant electrical,
546 mechanical, and thermal safety guidelines in the intended use environment.

547
548 The Verasonics system (Vantage 256TM) acts as a power source to activate the device. To maintain
549 electrical safety, the Verasonics uses TDK/Lambda CSS500-12 OEM power supply to provide an
550 alternating current line input that is “medical grade” in terms of leakage current and other
551 regulatory requirements. The maximum current passing through the human body and its duration
552 should be carefully considered to prevent any electrical hazard. The Verasonics system itself has
553 a power output threshold of 96 V, and the maximum current from this supply is 0.5 A. The patch
554 is activated at a maximum of around 20 V with a low pulse current (<100 μ A), far below the limit.
555 Specifically, the voltage source is in a pulsed mode, indicating that the transducers are vibrating
556 in a transient manner. The repetitive activation of the transducers, i.e., its pulse repetition
557 frequency, is 3000 Hz, which means that the transducers have 3000 working cycles per second.
558 The transient working state of the device implies that the conformal ultrasound patch will
559 experience an ultra-short (1.5 μ s) stimulation period (i.e., three cycles) in each working pulse. In
560 the pulsed excitation scheme, 99.55% of the time, no voltage is applied to the transducers, and thus
561 no current will flow across the human body. Considering the low current amplitude and its short
562 duration, the conformal ultrasound patch, even in case of a leakage, will not harm the operator or
563 the patient. In fact, the device is fully encapsulated by Ecoflex silicone, which is a superb insulator.
564 Therefore, the conformal ultrasound patch is safe for the human body.

565
566 The acoustic exposure of the device was evaluated using an ultrasound mapping system. We used
567 a hydrophone controlled by a 3D linear motor in a water tank to measure the acoustic signal
568 intensity (Extended Data Fig. 2). The waveforms exhibited very little nonlinear distortion and were
569 relatively narrowband (Supplementary Fig. 3) so that pressures could be estimated without
570 requiring deconvolution of voltage waveforms with frequency-dependent sensitivity⁵⁹.
571 Additionally, because the ratio of the hydrophone (HNP-0400, ONDA) sensitive element diameter
572 d_g to the product of the wavelength λ and $F/\#$ (ratio of focal distance to aperture width) was much
573 less than one, a hydrophone spatial averaging correction was not necessary⁶⁰.

574
575 Considering the capacitive load of the preamplifier (AH-2010-100, ONDA) when converting the
576 voltage measurements to pressure values, the loaded sensitivity $M_L(f)$ can be estimated as:

577
578
579

617
618

$$M_L(f) = G(f)M_c(f) \frac{C_H}{C_H+C_A+C_C} \quad (3)$$

where $G(f)$ is the preamplifier gain (20 dB in this study), $M_c(f)$ is the hydrophone end-of-cable open circuit sensitivity ($2.512 \times 10^{-8} \text{ V}\cdot\text{Pa}^{-1}$ at 2 MHz in this study), C_H is the capacitance of hydrophone (70 pF in this study), C_A is the capacitance of preamplifier (7 pF in this study), and C_C is the capacitance of connector (zero in this study because the preamplifier is connected directly to the hydrophone)⁶¹.

The pressure variables can be estimated as:

$$p(z) = \frac{V_{output}(z)}{M_L(f)} \quad (4)$$

where $V_{output}(z)$ is the output voltage, and z is the depth. The derated pressure variables can be estimated as:

$$p_\alpha(z) = p(z)10^{(-\alpha z f_{awf}/20\text{dB})} \quad (5)$$

Where α is the attenuation coefficient ($0.3 \text{ dB}\cdot\text{cm}^{-1}\cdot\text{MHz}^{-1}$)³³, and f_{awf} is the acoustic working frequency (2 MHz in this study)⁶².

The maximum derated spatial peak pulse average intensity, spatial peak temporal average intensity, and mechanical index should be measured on the worst-case pulse⁶³. Therefore, we focused the matrix array at 40 mm (i.e., the shallowest focal depth for a spectral Doppler pulse used in this study) and these parameters were measured at depth of the maximum value of the attenuated pulse pressure squared integral,

$$ppsi_\alpha(z) = \int p_\alpha^2(z, t) dt \quad (6)$$

where $ppsi$ is attenuated at α and z is varied from the break-point depth, z_{bp} , to the focal depth (40 mm in this study). The z_{bp} is defined as:

$$z_{bp} = 1.5 \times D_{eq} \quad (7)$$

where D_{eq} is the equivalent aperture diameter and is defined as:

$$D_{eq} = \sqrt{\frac{4}{\pi} A} \quad (8)$$

where A is the area of aperture. Plugging 144 mm^2 as the area of aperture in this study, z_{bp} can be estimated as 20.31 mm.

The pulse intensity integral is defined as:

$$pii_\alpha(z) = \frac{1}{\rho c} ppsi_\alpha(z) \quad (9)$$

where ρ is the density of water ($997 \text{ kg}\cdot\text{m}^{-3}$ in this study), and c is the speed of sound in water ($1480 \text{ m}\cdot\text{s}^{-1}$ in this study). Therefore, the derated spatial peak pulse average intensity is defined as:

$$I_{SPPA,\alpha}(z) = \frac{1}{t_d(z)} pii_\alpha(z) \quad (10)$$

where $t_d(z)$ is the pulse duration, which is 1.25 multiplied by the interval between the time when the time integral of the square of the instantaneous acoustic pressure reaches 10% and 90% of its final value⁶³. And the derated spatial peak temporal average intensity can be approximated as:

$$I_{SPTA,\alpha}(z) = PRF pii_\alpha(z) \quad (11)$$

where PRF is the pulse repetition frequency (3000 Hz in this study).

Based on the scanning result from the ultrasound mapping system, the maximum value of the attenuated pulse pressure squared integral was located at around 30 mm depth. Plugging the output

619 voltage 0.3274 V, and pulse duration 5.0563 μ s, the maximum derated spatial peak pulse average
620 intensity was 24.54 W/cm², and the maximum derated spatial peak temporal average intensity was
621 372.21 mW/cm².

622
623 The mechanical index (*MI*) indicates the likelihood of producing micromechanical bio-effects,
624 such as cavitation-related damage^{33,64}. The *MI* is defined as:

$$625 \quad MI = \frac{p_{r,\alpha}(z)}{\sqrt{f_{awf}}} \quad (12)$$

626 where $p_{r,\alpha}$ is the derated peak rarefactional pressure (i.e., the maximum negative instantaneous
627 acoustic pressure in an acoustic field) in MPa, and f_{awf} is measured of acoustic working frequency
628 in MHz. Plugging the derated peak rarefactional pressure 0.9968 MPa, the *MI* can be estimated as
629 0.70.

630
631 The relevant derated acoustic exposure maximum recommended levels are $I_{SPTA,\alpha} \leq 720$ mW/cm²
632 and $I_{SPPA,\alpha} \leq 190$ W/cm² or $MI < 1.9$ as defined by the Food and Drug Administration if scanning is
633 not performed through the orbital window³³. The maximum $I_{SPTA,\alpha}$, $I_{SPPA,\alpha}$, and *MI* of the
634 ultrasound patch were measured as 372.21 mW/cm², 24.54 W/cm², and 0.70, respectively, which
635 were all lower than the maximum recommended levels (Extended Data Fig. 2). Uncertainties in
636 these measurements are assumed to be on the order of 15%⁵⁹. Those values were reduced
637 significantly when the ultrasound waves propagated through a temporal bone. If scanning is
638 performed through the orbital window, the relevant derated acoustic exposure maximum
639 recommended levels are $I_{SPTA,\alpha} \leq 17$ mW/cm² (Food and Drug Administration Track 1) or 50
640 mW/cm² and *TI* (thermal index, see below) ≤ 1 (Food and Drug Administration Track 3) and
641 $I_{SPPA,\alpha} \leq 28$ W/cm² or $MI < 0.23$ (Food and Drug Administration Track 1 and Track 3). When
642 scanning through the orbital window, acoustic output was reduced to be below these levels.

643
644 To characterize thermal safety of the device, we measured its temperature rise when it was attached
645 to the skin. The thermal imaging results showed minimal temperature variation (< 1 °C) on the skin
646 surface when the device was attached to the temporal window and worked for four hours
647 continuously (Supplementary Fig. 12).

648
649 In addition, the thermal index *TI* was calculated to estimate tissue temperature rise⁶⁵:

$$650 \quad TI = \frac{\text{Acoustic power output}}{\text{Acoustic power output to produce } 1^\circ\text{C rise}} \quad (13)$$

651 Specifically, the *TI* estimates the temperature increase in the worst-case scenario by assuming the
652 tissue attenuation is homogeneous with an attenuation coefficient of 0.3 dB·cm⁻¹MHz⁻¹ while most
653 soft tissues have higher attenuation coefficients³³. Therefore, in most cases, the *TI* overestimates
654 the temperature increase compared to the real scenario. The Food and Drug Administration
655 guidance recommends a maximum *TI* of one when scanning through the orbital window. For
656 scanning through skull, it does not have a specific recommendation for maximum *TI* but requests
657 an explanation for *TI* over six³³. Using the output display standard (Track 3), the *TI* is required to
658 be provided and updated in real time on the acoustic output information screen to provide
659 ultrasonographers with an index for relative temperature change for a particular ultrasound
660 mode^{33,65}. The ultrasonographer uses this number and the ALARA (as low as reasonably
661 achievable) principle³³ to limit the scanning time and exposure level. According to an official
662 statement of the American Institute of Ultrasound in Medicine⁶⁶, for adult transcranial ultrasound,

663 there is no dwell time limit for $TI \leq 1.5$, max dwell time < 120 min for $1.5 < TI \leq 2.0$, max dwell time
 664 < 60 min for $2.0 < TI \leq 2.5$, max dwell time < 15 min for $2.5 < TI \leq 3.0$, max dwell time < 4 min for
 665 $3.0 < TI \leq 4.0$, max dwell time < 1 min for $4.0 < TI \leq 5.0$, max dwell time < 15 s for $5.0 < TI \leq 6.0$, and
 666 scanning with $TI > 6.0$ is not recommended⁶⁶.

667
 668 Depending on the tissues in the scanning plane, TI is subdivided into 3 types: soft tissue TI (TIS),
 669 bone TI (TIB), and cranium TI (TIC)⁶⁷. TIC is relevant for scanning through skull bone, and TIS
 670 is relevant for scanning through the orbital window. Thus, for TCD applications, TIS and TIC
 671 were calculated for long-term spectral Doppler monitoring.

$$672 \quad TIS_{as,ns} = \frac{P_{1 \times 1} \cdot f_{awf}}{210mWMHz} \quad (14)$$

673 where $TIS_{as,ns}$ is the TIS at surface in non-scanning mode (i.e., Doppler mode) and $P_{1 \times 1}$ is the
 674 bounded-square output power over a one square centimeter area in mW.

$$675 \quad TIS_{bs,ns} = \min \left[\frac{P_a(z_{s,ns}) \times f_{awf}}{210mWMHz}, \frac{I_{spta,\alpha}(z_{s,ns}) \times f_{awf}}{210mWcm^{-2}MHz} \right] \quad (15)$$

676 where $TIS_{bs,ns}$ is the TIS below surface in non-scanning mode, $P_a(z_{s,ns})$ is the derated output
 677 power at depth $z_{s,ns}$, and $I_{spta,\alpha}(z_{s,ns})$ is the derated spatial peak temporal average intensity at
 678 depth $z_{s,ns}$. Depth $z_{s,ns}$ is defined as:

$$679 \quad z_{s,ns} = \text{depth of } \max \{ \min [I_{spta,\alpha}(z) \times 1 \text{ cm}^2, P_a(z)] \} \quad (16)$$

680 where z is varied from z_{bp} and onward.

$$681 \quad TIC = \frac{P/D_{eq}}{40mWcm^{-1}} \quad (17)$$

682 where P is output power in mW. The power values $P_{1 \times 1}$, P , and $P_a(z_{s,ns})$ were measured from
 683 transverse hydrophone scans of the intensity distribution of the focused wave. P and $P_a(z_{s,ns})$
 684 were integrated over a transverse plane from the peak intensity distribution over a beam cross-
 685 sectional area in which the intensity was at least -26.2 dB of the maximum (axial) value. $TIS_{as,ns}$
 686 can be calculated as 0.62, $TIS_{bs,ns}$ as 0.10, and TIC as 0.38. These values were all far below the
 687 thresholds recommended by American Institute of Ultrasound in Medicine for long-term
 688 monitoring (i.e., $TI \leq 1.5$)⁶⁶.

690 **Supplementary Discussion 8: Coherent compounding**

691 Conventionally, an ultrasound image is obtained by a focused wave scanning line by line at
 692 different lateral positions (Supplementary Fig. 14). This method tremendously sacrifices the
 693 temporal resolution to generate an optimal image because numerous transmission and receiving
 694 events are required (Supplementary Fig. 14).

695
 696 Coherent compounding is a method that combines backscattered echoes from several different
 697 angles of insonation to produce a single image with higher object conspicuity (i.e., object to
 698 background contrast)⁶⁸. The speckle, clutter, and other acoustic artifacts may have different
 699 patterns (i.e., different phases) from different insonation angles. Combining the received echoes
 700 from a few different angles of insonation will enhance the target signals and reduce the artifacts,
 701 therefore increasing the image quality. For a given image quality, because less transmission and
 702 receiving events are required for coherent compounding based on diverging waves, it substantially
 703 increases the frame rate compared to conventional imaging using focused waves⁶⁸.

704

705 **Supplementary Discussion 9: Spatiotemporal clutter filtering for ultrafast Doppler imaging**

706 Ultrafast ultrasound imaging introduces a new paradigm for Doppler imaging^{69,70}. By using
707 diverging wave transmissions, it enables the acquisition of a large number of backscattered echoes
708 at a very high frame rate in all fields of view, which significantly increases the sensitivity of
709 Doppler shift⁷⁰.

710
711 In a Doppler image, clutter refers to stationary and slowly moving tissues whose signals need to
712 be removed to highlight blood flow signals and visualize vessels precisely⁷¹. Conventional clutter
713 filtering assumes that tissue motion signals and blood flow signals have completely different
714 spectral characteristics. The tissue motion is very slow whereas red blood cells are moving fast,
715 meaning that demodulated tissue motion signals and blood flow signals would not overlap.
716 Therefore, theoretically, tissue motion signals could be simply removed by a high-pass filter. In
717 reality, however, tissue motion and blood flow signals have overlap, which makes it impossible to
718 separate them based on temporal information only^{71,72}.

719
720 In this work, we considered the spatiotemporal characteristics of tissue motion signals, which are
721 different from those of blood scatterers. Tissue motion is spatially coherent, which means that
722 tissue movement tends to drive the surrounding tissues to move in the same way/direction because
723 of the cohesive nature of tissues⁷¹. These movements can be seen as a spatial shift of a group of
724 speckles. On the other hand, the motion of red blood cells represents a reorganization of the
725 scatterers and does not exhibit this spatial coherence⁷¹. Therefore, adopting such spatiotemporal
726 information for clutter filtering can potentially improve the separation of tissue motion and blood
727 flow.

728
729 Singular value decomposition is a mathematical operation on a matrix that can be used as a clutter
730 filter. This method decomposes a multi-dimensional matrix (e.g., 3D for space and one dimension
731 for time in this work) into a series of singular values and corresponding vectors. Because tissue
732 motion signals are highly correlated, the signals from different spatial pixels exhibit a high degree
733 of correlation and can be represented by larger singular values and corresponding vectors⁷¹. In
734 contrast, blood flow signals have much less spatial coherence and lower amplitudes, which can be
735 represented by smaller singular values and corresponding vectors⁷¹. Therefore, the singular value
736 decomposition can locate the higher covariance values, which represent the tissue motion signals
737 that can be removed⁷².

738
739 **Supplementary Discussion 10: Iteration of blood flow spectra processing**

740 Compared to other blood flow spectra that contain limited information⁴¹, we optimized the
741 algorithms for improving the blood flow spectra resolution and integrated necessary functions for
742 TCD sonography.

743
744 The conventional processing of blood flow signals simultaneously provides B-mode images, color
745 Doppler images, and spectrum Doppler waveforms⁴¹. Each modality requires the Verasonics
746 system to transmit and receive ultrasound waves and process the data separately. In this work, to
747 enhance the quality of blood flow spectra, we paused the B-mode and color Doppler imaging
748 processes and concentrated the computation power for spectra recording. The temporal resolution
749 of the spectra was increased from around 15 Hz to >200 Hz. The velocity resolution was improved

750 from around 4 cm/s to <0.01 cm/s. The intensity resolution reached the threshold of conventional
751 TCD probes (128-colormap)⁷³.

752

753 **Supplementary Discussion 11: Turbulent blood flow**

754 In turbulent flow, fluid varies chaotically in time and space, in contrast to laminar flow where the
755 fluid moves in smooth paths⁷⁴. These two types of flow can be differentiated by the Reynolds
756 number:

$$757 \quad Re = \frac{\rho V D}{\mu} \quad (18)$$

758 where ρ is the fluid density, V is the fluid velocity, D is the pipe diameter, and μ is the fluid
759 viscosity. In most physiological blood flow, Reynolds numbers are moderate and far below the
760 threshold of transitioning from laminar to turbulent flow (i.e., 2300)⁷⁵. However, at sites of stenosis,
761 the blood flow velocity is inversely proportional to the square of the vessel diameter, which results
762 in a higher flow velocity, a higher Reynolds number, and thus a higher likelihood of generating
763 turbulent flow. Downstream from the stenosis, the blood flow velocity remains high, and the vessel
764 diameter becomes larger when entering this region, yielding an even larger Reynolds number and
765 often turbulent flow.

766

767 These two types of flow have different patterns in the Doppler spectra⁷⁶. For laminar flow, most
768 of the scatters are of high velocities in the same direction. Thus, the spectra have a high intensity
769 zone near the maximum velocity. For turbulent flow, these particles rotate and form a wide range
770 of Doppler angles to the ultrasound beam, and therefore cover the entire range of velocities in the
771 spectra.

772

773 **Supplementary Discussion 12: Success rate of TCD sonography**

774 TCD is a widely accepted method for monitoring cerebral blood flow. Its effectiveness, however,
775 is intrinsically limited by the acoustic properties of the skull⁷⁷. TCD uses specific skull areas,
776 known as acoustic windows, which usually possess anatomical features conducive to the
777 satisfactory transmission of ultrasound beams. Still, significant attenuation and phase aberration
778 of the ultrasound beam by the skull may prevent adequate detection, leading to the failure of TCD
779 examinations. The attenuation and phase aberration are largely influenced by the skull's structure,
780 which reflects, absorbs, and scatters the ultrasound beam (Supplementary Figs. 2 and 3, and
781 Supplementary Discussions 2 and 3).

782

783 Demographic factors such as sex, age, race/ethnicity, and the presence of specific diseases
784 drastically impact skull structure. Women, for instance, tend to have thicker temporal bones than
785 men⁷⁸, with a decrease in bone density, especially after menopause⁷⁹. Aging increases the risk of
786 examination failure due to temporal bone thickening and reduced bone density^{77,80}. Additionally,
787 racial and ethnic differences also affect temporal bone thickness and density^{81,82}. Conditions like
788 osteoporosis significantly influence the texture of the temporal bone's middle layer, further
789 complicating the variations in skull structure^{80,81}.

790

791 Two primary strategies have been explored to overcome these limitations: increasing the acoustic
792 intensity and using contrast agents. Increasing acoustic intensity will improve the success rate^{83,84}
793 but must remain within safe limits recommended by the Food and Drug Administration Track 1
794 (i.e., 720 mW/cm²) to avoid tissue damage³³. Contrast agents, while enhancing ultrasound

795 reflection, raise concerns about patient safety and procedural complexity and are not commonly
796 used in TCD examinations⁸⁵.

797
798 To elucidate the impact of these on success rate of TCD examination, we have summarized
799 relevant exemplary large group studies (Extended Data Table 2). This table reveals a marked
800 association between these variables and the success rate, highlighting the critical role of participant
801 characteristics in determining TCD outcomes. However, it's important to acknowledge the
802 limitations of such data. First, while extensive, these studies are subject to potential selection bias
803 due to their reliance on data from a single research site/institution. Secondly, the term 'success rate'
804 lacks a standardized definition across studies, leading to inconsistencies in data interpretation.
805 Some research defines it as the ability to acquire optimal signals through the temporal window^{80,85},
806 while others consider both optimal and suboptimal (e.g., only part of the arterial segments cannot
807 be accessed) signal acquisitions as a measure of success^{86,87}. Additionally, distinctions are made
808 between acquiring signals from one⁸⁴ or both⁸⁸ sides of the temporal window. To enhance
809 comparability with most of the existing studies, the definition of 'success rate' in the current study
810 is the ability to acquire either optimal or suboptimal signals through both sides of temporal window.
811 The definition of success rate for each study has been specified as clearly as possible (Extended
812 Data Table 2). Thirdly, there's a notable lack of information on variables like intensity level,
813 race/ethnicity, and medical history, leading to gaps in the dataset. These gaps lead to an incomplete
814 understanding of how different factors affect success rates, potentially skewing comparisons.
815 Despite these limitations, the table still offers a reliable overview of TCD examination outcomes.
816 Notably, our findings are in line with existing research, underscoring the technical robustness and
817 reliability of our device.

818
819 Note that in this study, we also compare the success rate of soft ultrasound devices (72.2%), which
820 utilize two-dimensional matrix arrays, to the conventional rigid TCD probes (77.8%), which are
821 based on phased array or single-element probes. While the soft probes promise enhanced
822 accessibility and ease of use, they exhibit a slightly lower success rate because of the smaller
823 element size of matrix arrays^{89,90}. The smaller size results in higher impedance, leading to a larger
824 impedance mismatch between the transducer element and the circuit. This mismatch, in turn,
825 causes energy loss during the transmission and reception of ultrasound signals.

826

827 **Supplementary Discussion 13: Pulsatility index and resistive index**

828 The pulsatility index (*PI*) and the resistance index (*RI*) describe the spectral profile. They can be
829 calculated as:

830
$$PI = \frac{(V_s - V_d)}{V_m} \quad (19)$$

831
$$RI = \frac{(V_s - V_d)}{V_s} \quad (20)$$

832 where V_s , V_d , and V_m are the peak systolic, end diastolic, and mean flow velocities, respectively.
833 The *PI* and the *RI* are closely related to each other and are mainly affected by the differences in
834 systolic and diastolic flow velocities. The end diastolic velocity is the residual flow velocity during
835 diastole, reflecting the impedance of the vascular bed⁹¹. Under normal circumstances, the *PI* and
836 the *RI* of intracranial vessels are smaller than those of extracranially and peripherally due to the
837 low resistance at the distal end of the intracranial vessels. When the resistance of vascular bed
838 increases, the spectra show low diastolic blood flow, and the *PI* and *RI* increase, and vice versa.
839 Abnormalities in these parameters may have pathological significance clinically⁹². Spectra of low

840 *PI* and *RI* can be seen in distal arteries with arteriovenous malformations, stenosis, and
841 occlusion^{91,93}. A significantly increased *PI* and *RI* has been observed in cases of increased
842 intracranial pressure and proximal arteries from severe aortic stenosis or occlusion sites^{91,93}.

843

844 **Supplementary Discussion 14: Cerebral blood flow regulation mechanisms**

845 Cerebral blood flow regulation means the cerebral vasculature can maintain blood flow
846 equilibrium despite changes in other physiological parameters (e.g., arterial pressure, intracranial
847 pressure, and blood viscosity). The net driving force of generating flow in cerebral arteries is
848 cerebral perfusion pressure, defined as the difference between arterial blood pressure and venous
849 blood pressure. The total cerebral blood flow is controlled by cerebral perfusion pressure and
850 cerebrovascular resistance. With the ever-changing cerebral perfusion pressure, the brain adjusts
851 cerebrovascular resistance, therefore maintaining stable blood perfusion.

852

853 Various processes, including myogenic, metabolic, endothelial, and neurogenic responses, have
854 been considered as potential mechanisms of cerebral regulation^{49,94}. The myogenic hypothesis
855 states that the cerebrovascular resistance change is provoked by variations in vascular smooth
856 muscle tone under different transmural pressures⁹⁵. Specifically, transmural pressure changes
857 initiate membrane depolarization, opens mechanically sensitive ion channels, generates an influx
858 of calcium ions, and triggers smooth muscle cells, resulting in cerebrovascular resistance changes.
859 The metabolic mechanism states that the regulation occurs in smaller vessels that are subject to
860 variations in the local environment⁹⁶. The concentration of cerebral CO₂ can accumulate and cause
861 vasodilation when hypotension results in tissue hypoperfusion and anaerobic respiration. The
862 opposite physiology appears in hyperperfusion with consequent decreases in CO₂ concentration
863 and vasoconstriction. Additionally, the endothelium can be provoked by different blood flow
864 patterns to secrete vasodilators and vasoconstrictors⁹⁷. Finally, neurogenic mediation of cerebral
865 vasoreactivity can alternate the vessel diameter⁹⁸. The variation in blood flow in response to
866 neuronal activation is reflected in blood oxygen level-dependent signals, which has been
867 investigated in cognition, memory, visual processing, and exercise. For example, the contraction
868 of skeletal muscle evokes the autonomic regulation. The hypothalamus that controls the autonomic
869 nervous system activates the sympathetic nervous system and restrains the parasympathetic
870 nervous system, leading to an increase in the blood supply to the brain. The conformal ultrasound
871 patch with high spatiotemporal resolutions can potentially be a powerful tool for observing these
872 acute blood flow changes and studying relevant cerebral regulation mechanisms.

873

874 **Supplementary Discussion 15: Intracranial B waves**

875 The glymphatic system plays a major role in removing waste products and metabolic debris from
876 the central nervous system during sleep⁹⁹. To do this, the glymphatic system controls the
877 cerebrospinal fluid flows through the brain parenchyma for material exchange. While the
878 cerebrospinal fluid interacts with the interstitial fluid surrounding the brain cells, it transports those
879 waste or toxic substances from the interstitial fluid to the lymphatic vessels. This process involves
880 the slow oscillations of the cerebrospinal fluid. Because the brain and spinal cord are surrounded
881 by the cerebrospinal fluid, such slow oscillations can be directly reflected by the intracranial
882 pressure change and similar fluctuant patterns in cerebral blood flow. These patterns have a typical
883 frequency range from 0.3 to 4 cycles per min and are called intracranial B waves^{100,101}.

884

885 The dysfunction in cerebrospinal fluid generation or draining commonly accompanies aging,
886 Alzheimer's disease, and sleep disturbances^{102,103}. Therefore, continuous monitoring of intracranial
887 B waves in sleep studies can be used to evaluate the functionality of the brain in neurodegeneration
888 and other neurological pathologies, and also evaluate the effectiveness of strategies to enhance
889 cerebral blood flow and cerebrospinal fluid oscillations to improve lymphatic flow.
890

891 **Supplementary Discussion 16: Application of the conformal ultrasound patch**

892 TCD sonography represents a safe, relatively inexpensive, and reliable method to measure cerebral
893 hemodynamics⁴⁸. It is the standard of care in the clinical setting and is a powerful tool for
894 neurovascular studies¹⁰⁴. Compared to conventional rigid and bulky TCD probes, the conformal
895 ultrasound patch represents a platform technology for volumetric vascular network reconstruction
896 and continuous long-term monitoring of blood flow spectra. This technology not only qualifies for
897 use cases of existing TCD probes but also enables new applications that are challenging or
898 impossible for existing counterparts.
899

900 The conformal ultrasound patches eliminate the user-dependency as typically seen in the
901 conventional TCD probes. For placing the device, the ultrasound patch only needs to be attached
902 to transcranial windows, and the ultrasound waves can be electrically focused on the target arterial
903 segment based on 3D phased array control. In contrast, the conventional TCD probe requires a
904 well-trained operator to manually tilt the probe to find the blood flow signal from the target arterial
905 segment.
906

907 For blood flow monitoring, conventional TCD probes must be manually fixed by the operator or
908 a rigid headset. Minor handshaking or head movement may result in misalignment between the
909 ultrasound beam and target artery, leading to signal loss. In contrast, the ultrasound patch, designed
910 to comfortably attach to the scalp, offers a much-increased tolerance for motion artifacts.
911

912 For the identification of target arterial segments, conventional TCD probes typically use a single
913 transducer or a linear array of transducers, which can only image part of the intricate 3D network
914 of cerebral arteries (Extended Data Fig. 1). Different operators may acquire signals from different
915 segments of the 3D network, strongly affecting repeatability and reproducibility of the result. The
916 volumetric imaging approach addresses this problem by depicting the 3D network to guide target
917 segment identification, thus substantially reducing operator dependency.
918

919 The conformal ultrasound patches may allow earlier and continued evaluation of cerebral
920 perfusion in emergency rescue settings¹⁰⁵. The most immediate application is for long-term
921 monitoring of patients following subarachnoid hemorrhage^{106,107}. In well-resourced hospital neuro
922 intensive care units, TCD is used routinely in these cases to serially assess for vasospasm after
923 injury and provide information as to response to interventions¹⁰⁸. However, this type of
924 measurement is resource-intensive, operator-dependent, and although continuous during the
925 measurement period, is essentially point-in-time as far as detecting changes in patient condition.
926 There is thus a large unmet need for low-profile devices with capability for long-term (e.g., several
927 days) continuous measurement of cerebral blood flow.
928

929 Other immediate applications for conformal ultrasound patches include emboli detection,
930 particularly during the peri-operative period and in procedures involving the aortic arch as well as

931 those with large embolic burden (e.g., orthopedics). Emboli emanating from elsewhere in the
932 vasculature can travel to the brain, blocking cerebral arteries and blood flow, with deleterious
933 consequences if not properly monitored or diagnosed^{109,110}. Emboli to the brain can be initially
934 asymptomatic but may develop into transient ischemic attack or stroke. Having the ability to
935 monitor emboli continuously in high-risk patients for long periods of time can provide insights
936 into the mechanisms of embologenesis and propagation as well as provide timely feedback for
937 therapeutic interventions. Specifically, the occurrence of emboli during and after mechanical
938 thrombectomy may suggest inadequate anticoagulation and/or antiplatelet therapy, and may lead
939 to pharmacological adjustment¹¹¹. The presence of emboli has also been shown to predict new
940 embolic events¹¹². During and after carotid stenting or carotid endarterectomy procedures,
941 continuous and long-term monitoring of emboli can provide timely feedback to the
942 interventionalist/surgeon and allow anti-platelet therapy optimization and/or re-exploration^{113,114}.
943 Importantly, blood flow monitoring of the operative site may reveal the integrity of vascular
944 perfusion in the event of temporary surgical carotid occlusion. Similarly, coiling of cerebral
945 aneurysms can be associated with the occurrence of emboli.

946
947 Furthermore, continuous long-term post-procedure cerebral blood flow monitoring based on the
948 conformal ultrasound patch is suggested for patients experiencing early neurological deterioration
949 after thrombectomy or stenting. This monitoring provides important insights into conditions like
950 hyperperfusion syndrome, intracranial steal syndrome, post-stent re-occlusion, and facilitates the
951 comparison of collaterals over time on both sides. The prolonged monitoring helps assess the status
952 of leptomeningeal collaterals in patients with large vessel occlusions who have undergone
953 successful thrombectomy. Another group of patients that could significantly benefit from long-
954 term TCD monitoring are those with recurrent transient ischemic attacks of unknown origin. In
955 these cases, this protocol can effectively assist in ruling out transient emboli signals versus
956 vasospasm in proximal vessels. Due to technical challenges and dependence on operator skill with
957 the current TCD device, long-term blood flow monitoring in these mentioned conditions is not
958 feasible. Consequently, critical information regarding brain hemodynamics during the acute phase
959 of stroke patients is being missed.

960
961 The technology is also particularly useful for the diagnosis of transient ischemic attacks and
962 embolic strokes from atrial fibrillation¹¹⁵. Continuous monitoring over an extended period would
963 allow for confirmation of emboli as the cause of transient ischemic attack symptoms,
964 distinguishing between embolic and hemodynamic causes of the symptomatology. Continuous and
965 long-term monitoring cerebral blood flow may also reduce the impact of resulting strokes, during
966 atrial fibrillation ablation procedures¹¹⁶ and orthopedic procedures¹¹⁷ where fat or cement emboli
967 are a well-recognized complication. Finally, combining the blood flow and arterial wall pulsation
968 measurements of the ICA can be used to estimate intracranial pressure non-invasively^{118,119}. The
969 potentially benefited areas include but are not limited to carotid and coronary artery stenosis¹²⁰,
970 cerebral hemorrhage¹²¹, antithrombotic treatment¹²², and complications associated with surgical
971 procedures^{123,124}, invasive examinations¹²⁵, sequelae of orthopedic¹²⁶, and obstetric
972 procedures^{127,128}.

973
974 Beyond its conformability for continuous long-term monitoring, this technology is capable of
975 imaging cerebral blood volume at high spatiotemporal resolutions, which is not available by
976 existing TCD sonography.

977

978 The brain poses a significantly greater challenge for ultrasound sensing due to the skull-induced
979 strong acoustic attenuation and aberration (Supplementary Figs. 2 and 3, and Supplementary
980 Discussions 2 and 3). Additionally, volumetric imaging requires the simultaneous individual
981 control of each transducer element in the two-dimensional matrix array, which significantly
982 degrades the signal quality. Traditional beamforming focuses the ultrasound waves on a particular
983 point in space. In volumetric imaging, this needs to be done in 3D, requiring the simultaneous
984 control of a significantly larger number of transducer elements. Ensuring that the ultrasound waves
985 from each element are correctly phased to maintain a tightly focused beam to scan in 3D can be
986 technically challenging, and errors in this process can lead to degradation in image quality. In
987 addition to software challenges, the simultaneous operation of closely packed transducers can lead
988 to crosstalk between elements, which may degrade the clarity of the ultrasound image by
989 introducing noise and artifacts.

990

991 To address these issues, we have applied the ultrafast ultrasound imaging technique^{69,70,129} to
992 further enhance blood flow signals acquired within the brain. Unlike traditional beamforming by
993 using focused beams, this cutting-edge technique employs a sequence of diverging beams. This
994 approach allows simultaneous data capture from the entire field of view with a single transmission,
995 resulting in significantly faster image reconstruction and enhanced computational efficiency.
996 Additionally, the high-speed nature of this technique allows imaging at extraordinarily high frame
997 rates, often reaching over a thousand frames per second. Integrating the singular value
998 decomposition⁷¹ with such high-speed imaging enables the capture of rapid physiological
999 phenomena such as blood flow dynamics in the cerebral vasculature even through the skull.
1000 Moreover, we have implemented a multilayered stretchable electrode with a well-designed copper
1001 mesh electromagnetic shielding layer. This design allows for the individual activation of each
1002 element in the two-dimensional matrix array while increasing the signal-to-noise ratio by an
1003 average of 5 dB.

1004

1005 The volumetric imaging allows accurate identification of the monitoring target, eliminating the
1006 user-dependency as typically seen in the one- or two-dimensional imaging of conventional TCD
1007 probes. The volumetric information can potentially help diagnose vascular diseases such as
1008 stenosis, ischemia, and subarachnoid hemorrhage, which correlate with almost imperceptible
1009 variations in vessel morphology and blood perfusion amplitude^{27,105,130}. Even though they are not
1010 generated in real-time, this information could still be valuable under continuous monitoring and
1011 provides alerts of the emergencies.

1012

1013 Besides disease diagnosis, the conformal ultrasound patch can be used for functional TCD studies.
1014 The long-term conformability enables the device to be used for chronic awake studies on brain
1015 reactions. Taking advantages of the matrix array with the ultrafast Doppler imaging technique, the
1016 device allows monitoring cerebral functions in major arteries accurately in 3D, which is valuable
1017 for understanding how the brain works on a large scale under normal or pathological
1018 conditions^{89,131}. Combining the structural and dynamic information collected from the patch will
1019 generate a profound understanding of the interaction between the circulatory system and the brain.
1020 For example, this technology can be used to study functional connectivity when different stimuli
1021 are applied¹³²⁻¹³⁴. This technology can also be combined with real-time ultrasound localization
1022 microscopy to achieve much higher spatiotemporal resolutions for capillary blood flow mapping,

1023 which would be of great value for characterizing local neurovascular coupling¹³⁵⁻¹³⁷.
1024

1025 **Supplementary Discussion 17: Application feasibility and safety of microbubbles**

1026 Microbubbles, commonly known as contrast agents, have a limited duration within the human
1027 body. In our research, we demonstrated two distinct imaging modes: the 3D power Doppler
1028 imaging mode and the spectral Doppler mode. The former effectively captures the anatomical
1029 details of the circle of Willis, while the latter allows for the monitoring of blood flow in individual
1030 blood vessels. The 3D power Doppler mode was performed only once initially, specifically to
1031 localize the target blood vessels. This procedure requires less than 10 min, which is shorter than
1032 the typical duration of commonly used microbubbles³⁶. Because we utilized diverging waves in
1033 this mode and the operational time is brief, microbubbles hold promise as a potential enhancer for
1034 3D vascular network imaging in the power Doppler mode. On the other hand, the spectral Doppler
1035 mode employs a focused ultrasound beam to examine a specific region within the blood vessel,
1036 ensuring a high signal-to-noise ratio for continuous functional monitoring tests, without the need
1037 for microbubbles.

1038
1039 These air gas microbubbles have a typical diameter $<10\ \mu\text{m}$, enclosed in lipid, protein, or polymer
1040 shells³⁷. These small-sized microbubbles can easily pass through capillaries without impeding
1041 blood flow. Moreover, the microbubble shells are treated to prevent coalescence, often by
1042 incorporating Polyethylene glycol³⁸. As a result, under normal conditions, microbubbles remain
1043 stable without aggregating. However, microbubble coalescence may occur under specific
1044 insonation conditions, which depend on various factors such as frequency, pressure level, duty
1045 cycle, and microbubble concentration^{39,40}. Quantitative studies have been conducted to investigate
1046 these parameters in the context of imaging and therapy purposes⁴⁰. For example, low-frequency
1047 (about 1 MHz), low-amplitude (about 100 kPa) therapeutic ultrasound requires a high duty cycle
1048 ($>1\%$) and a high microbubble concentration level (about 2×10^8 bubbles/mL) to generate
1049 microbubble coalescences⁴⁰. Conversely, high-frequency (around 5 MHz), wide amplitude range
1050 (100 to 1,000 kPa) imaging ultrasound does not result in coalescence even at very high duty cycles
1051 (about 10%)⁴⁰. Most importantly, coalescence did not occur at any parameters when the
1052 microbubble concentration level is 2×10^6 bubbles/mL⁴⁰, approximating the concentration in
1053 human blood circulation⁴¹. In general, contrast-enhanced imaging mode, which utilizes higher
1054 frequency, lower duty cycle, and lower pressure, is less likely to generate coalescence compared
1055 to therapeutic ultrasound. In this study, although the frequency for transcranial ultrasound imaging
1056 is typically set at 2 MHz, there is room to control other parameters, such as pressure level and duty
1057 cycle within suitable ranges to decrease the possibility of coalescence. Properly using low-
1058 concentration microbubble solutions could be an effective approach to prevent coalescence.

1060 **Supplementary Discussion 18: Generation of harmonic components by microbubbles**

1061 The incident ultrasound waves can drive nonlinear vibrations of microbubbles^{138,139}. Microbubbles
1062 consist of gas encapsulated by a shell. If the incident wave is a sine wave and microbubbles vibrate
1063 linearly, the backscattered ultrasound wave will also be sine wave with the same frequency. The
1064 positive pressure corresponds to microbubble compression, while negative pressure corresponds
1065 to microbubble expansion. However, microbubbles are easy to expand, but not easy to compress.
1066 As a result, the backscattered waves will have a negative sine wave shape but modified positive
1067 wave shape. Therefore, the backscattered waves will be distorted, similar to but different from sine
1068 waves.

1069
1070 For the sine wave, it only has the frequency (i.e., the fundamental frequency) equal to the frequency
1071 of the incident wave. For the distorted backscattered wave, it still has the same vibration period as
1072 the sine wave, which is the fundamental frequency. On the other hand, the distorted wave contains
1073 harmonic frequencies if a Fourier transform is applied to the distorted wave.
1074

1075 **Supplementary Discussion 19: Fully integrated wearable ultrasound system**

1076 In the current design, the Verasonics system is still necessary to control the ultrasound patch and
1077 collect the data. Transcranial volumetric imaging requires a relatively high-power supply to make
1078 sure the transmitted ultrasound waves can successfully penetrate through the transcranial windows
1079 into the deep brain and be received for further data processing. Additionally, the volumetric
1080 ultrafast power Doppler imaging and long-term spectral Doppler monitoring can generate a large
1081 dataset (e.g., 1 to 5 GB), which requires a powerful system for fast data transfer and processing.
1082 Therefore, current device still faces challenges in terms of miniaturization of a control system and
1083 reduction of power consumption before it can be considered a truly wearable ultrasound system.
1084

1085 Recently, important strides have been made in this direction by developing a fully integrated
1086 wearable system⁴⁰. This system includes a stretchable ultrasound patch for ultrasound transmission
1087 and receiving, a flexible printed circuit board for data acquisition and wireless communication, a
1088 lithium-polymer battery for power supply, and a machine learning algorithm for data analysis. The
1089 system is capable of monitoring various physiological signals during motion, marking it a
1090 significant advancement in wearable ultrasound monitoring. However, one of the primary
1091 challenges faced by this fully integrated system is the incapability of volumetric imaging. The
1092 current design is optimized for M-mode imaging, which provides one-dimensional, depth-resolved
1093 images. While this is effective for monitoring certain physiological signals, it does not provide a
1094 comprehensive, 3D views of the tissues under observation. This limitation is primarily due to the
1095 complexities involved in implementing beamforming in a wearable ultrasound system. Traditional
1096 volumetric beamforming requires substantial computational resources and power, which are
1097 challenging to accommodate in a compact device.
1098

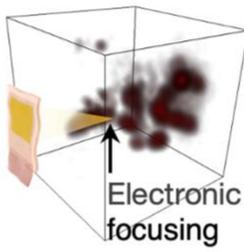

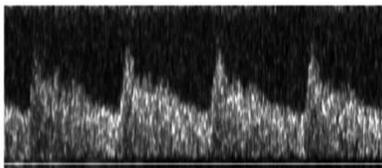

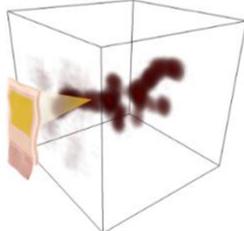

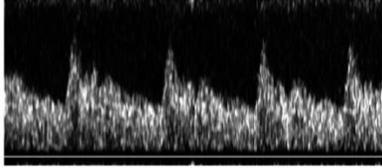

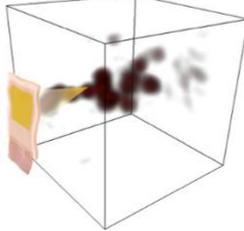

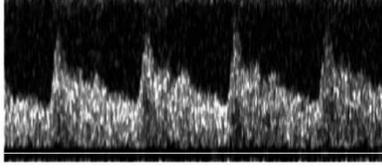

1099 Our ongoing efforts are focusing on more advanced beamforming methods. For example, the local
1100 micro-beamformer technique can simplify the overall system's computational complexity by
1101 conducting initial local beamforming on individual subarrays¹⁴⁰. This approach breaks down the
1102 beamforming process into smaller stages, reducing power consumption and making the technology
1103 more suitable for wearable applications. Similarly, multiplexing reduces hardware complexity by
1104 reducing the system size, decreasing the number of connections between the transducer and
1105 processor, consequently lowering power consumption through reduced bandwidth requirements
1106 for data transmission^{141,142}. The synthetic aperture method¹⁴³ minimizes hardware demands by
1107 simulating a larger, virtual array with a smaller physical array, improving imaging resolution and
1108 reducing power consumption due to fewer signal processing steps.
1109

1110 There are challenges associated with these techniques. The local micro-beamformer, for instance,
1111 can result in suboptimal image quality because of the approximations made during the localized
1112 beamforming process. The multiplexing techniques can lead to crosstalk or interference between
1113 channels, potentially degrading image quality as signals from different channels overlap or
1114 interfere with each other. Additionally, synthetic aperture methods, despite their improvements in

1115 imaging resolution and hardware requirements, require complex algorithms and substantial
1116 computational power to form the final image, which tends to be slower than conventional
1117 beamforming techniques as they necessitate multiple transmit and receive events. This can result
1118 in lower frame rates, which may affect real-time imaging applications.

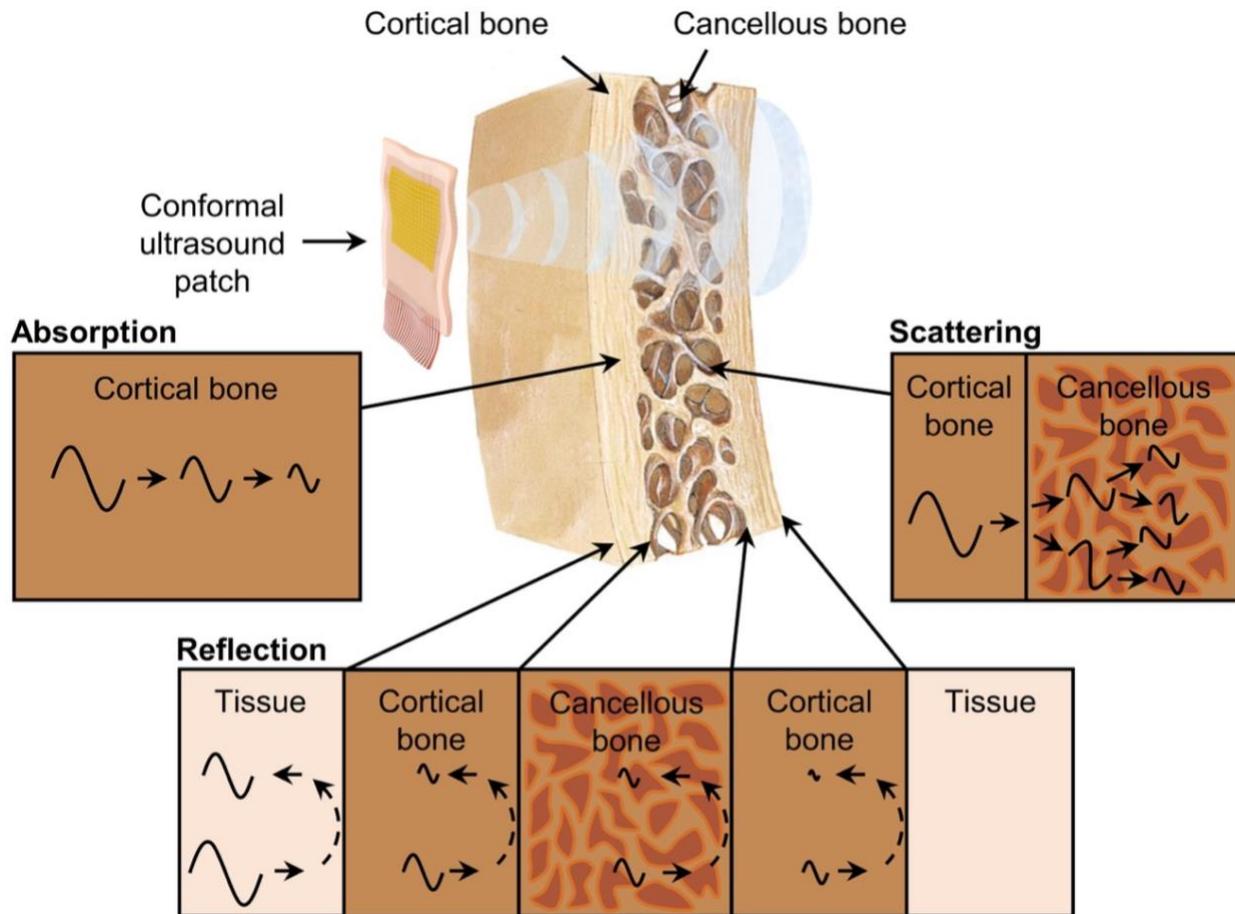

1119
1120 Therefore, while these advanced methods present promising solutions to the challenges of low
1121 power consumption and increased computational power to achieve volumetric imaging by using
1122 wearable ultrasound devices, we are working on addressing their drawbacks to optimize and
1123 balance these trade-offs, ultimately enabling wearable ultrasound technology to reach its full
1124 potential across a wide range of medical applications.

Supplementary Fig. 1 | Blood flow spectra with different device placement positions. Both the conventional TCD probe and the conformal ultrasound patch were tested at three distinct positions for recording blood flow spectra. While at position 2, the conventional TCD probe happened to yield a high-quality spectrum without the need for manual tilting, other positions necessitated manual tilting of the probe to find the optimal angle for quality spectra. This routine adjustment process is not only time consuming but also heavily dependent on the operator's experience and training. Conversely, the ultrasound patch leverages its volumetric imaging capability to electronically focus the ultrasound beams directly onto the target, streamlining the acquisition process. The blood flow spectra share the same scale bars.

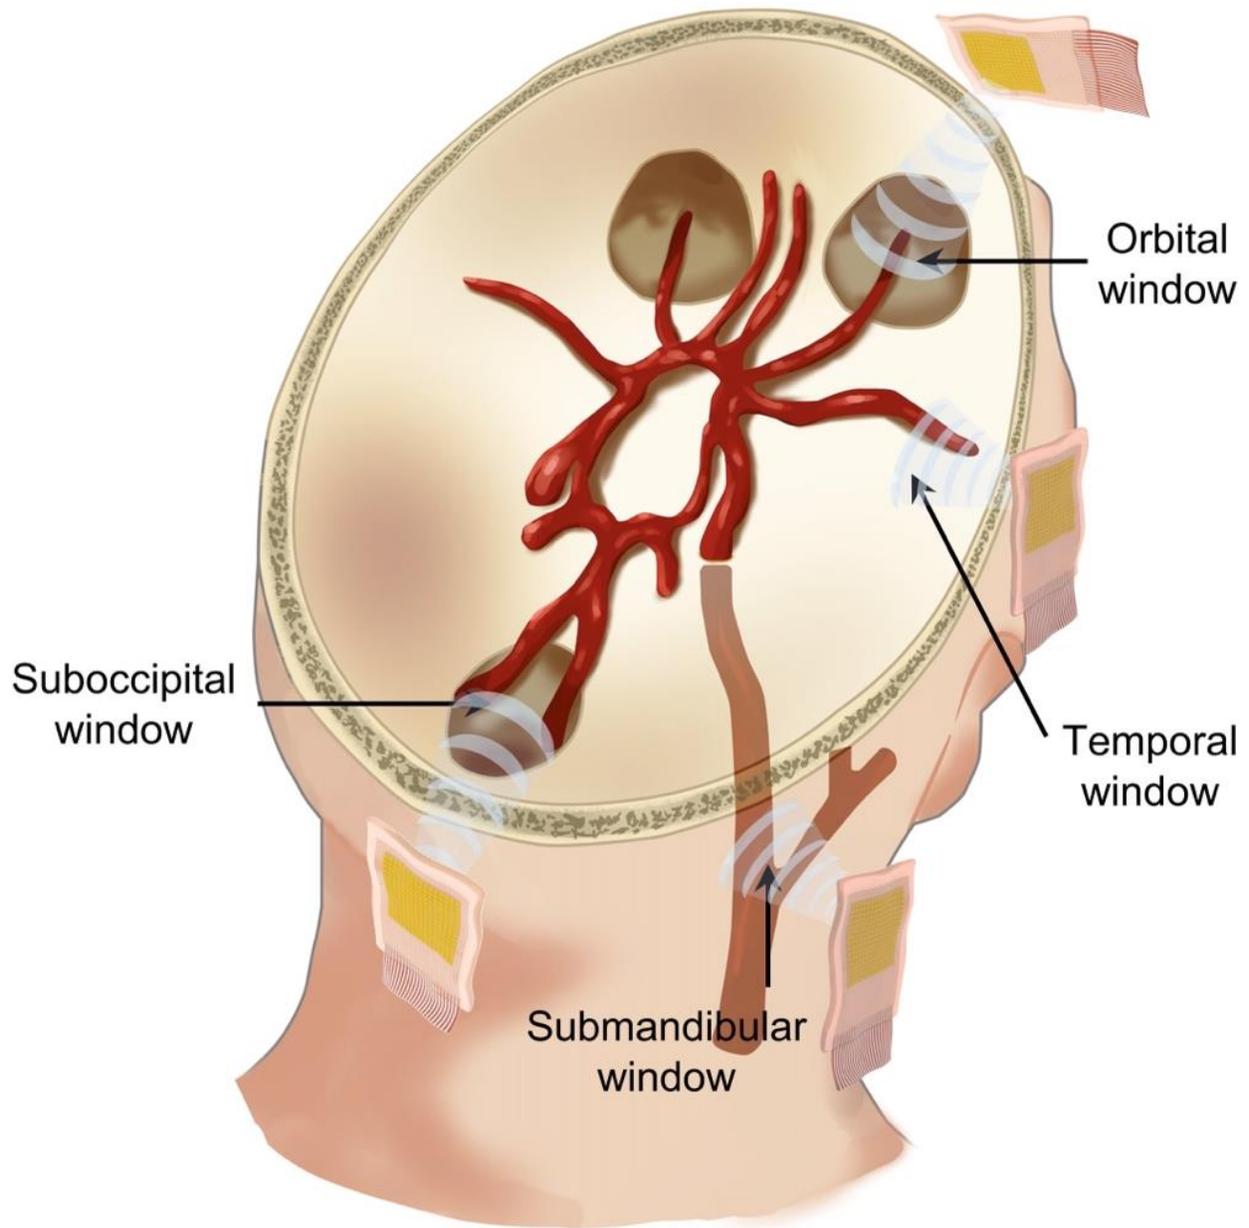

1135
 1136
 1137
 1138
 1139

Supplementary Fig. 2 | Acoustic attenuation by the skull. The skull causes three different types of attenuation, including reflection, absorption, and scattering. The scattering mainly happens in the cancellous bone. The reflection mainly happens at the interfaces between media with different acoustic impedances.

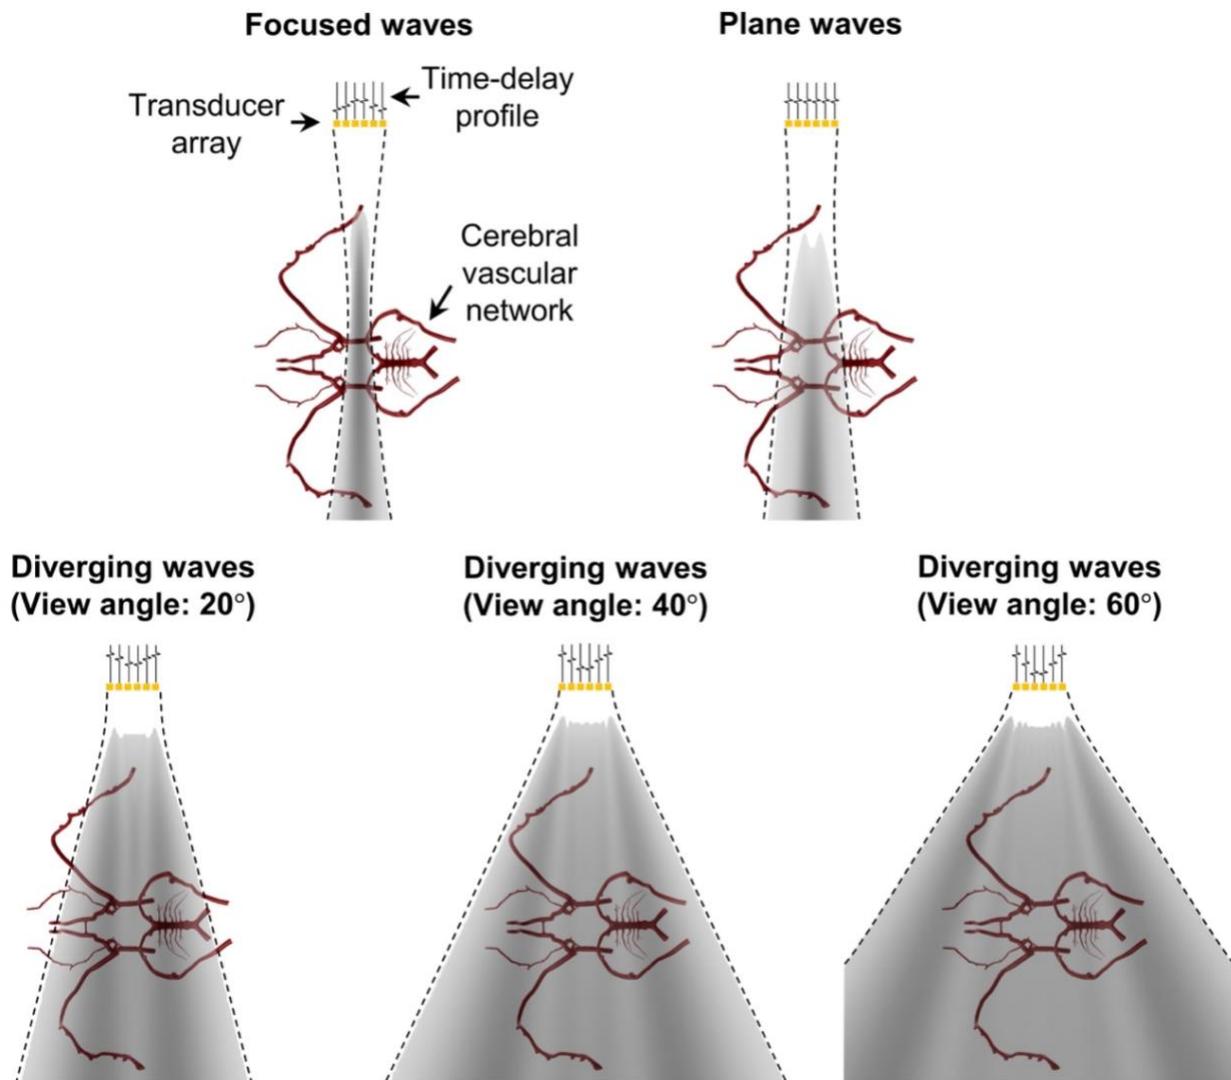

1140
 1141 **Supplementary Fig. 3 | Phase aberration of the skull with backscattered signals at different**
 1142 **ultrasound frequencies.** **a-b**, The transducer array can achieve reliable beamforming with well-
 1143 defined parabolic time-delay profiles while the target is within a homogeneous medium and the
 1144 surface is flat at both low and high ultrasound frequencies. Black lines and gray lines of the insets
 1145 at the upper right corners are the beam formed received signals. The insets at the lower left corners
 1146 show simulated beamforming results by the transducer array at low and high ultrasound
 1147 frequencies, respectively. **c-d**, The inhomogeneous composition, non-uniform thickness of the
 1148 skull, and non-flat surface induce aberration to beamforming, but with a less degree at low
 1149 frequency than at high frequency. Black dashed lines and gray dashed lines of the insets at the
 1150 upper right corners are the received signals with the same time-delay (Δt) but different phase shifts.
 1151 The insets at the lower left corners show the simulated beamforming results by the transducer array
 1152 at low and high ultrasound frequencies, respectively. We adopted an open-source Matlab toolbox

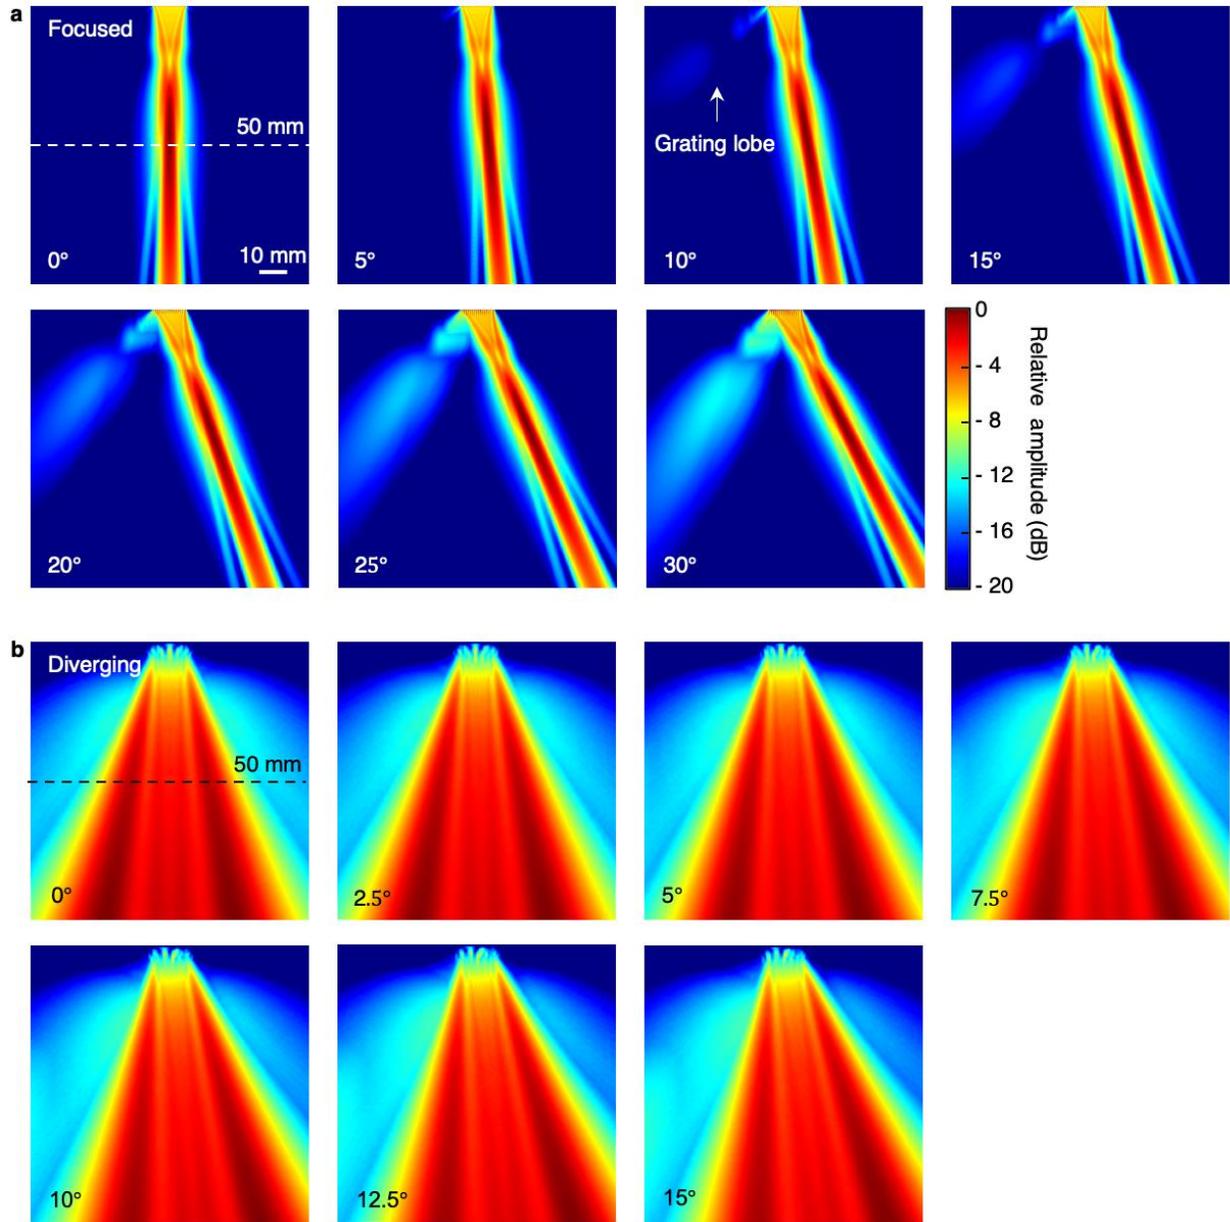

1153 k-Wave to simulate the influence of skull on the sound beams. This toolbox can set the sound
1154 speed and density of medium of every voxel in the space. The soft tissue background was also set
1155 as homogeneous with a sound speed of 1,540 m/s and a density of 1,000 kg/m³. A layer of bone
1156 with non-uniform thickness was created by setting the sound speed and density as 3,000 m/s and
1157 2,300 kg/m³, respectively⁴². We could also set the emitted waveform of each element to create a
1158 focused beam. All insets share the same scale bars.

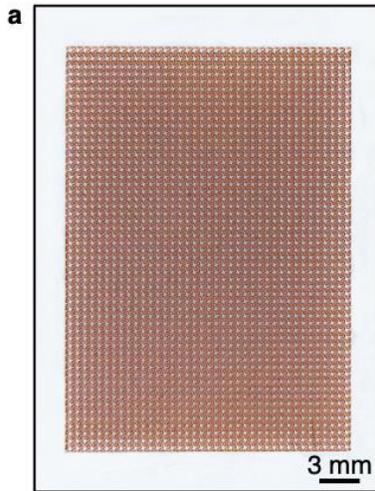

1159
 1160 **Supplementary Fig. 4 | The common transcranial windows with relatively low acoustic**
 1161 **attenuation and phase aberration for TCD sonography.** Through the orbital window, the
 1162 ultrasound beam is directed toward the optic canal and does not pass through the skull. When using
 1163 the temporal window, the ultrasound beam only needs to transmit through the thin temporal bone.
 1164 The submandibular window locates at the neck. Through this window, the ultrasound beam can
 1165 target at the internal carotid artery without transmitting through the skull. The participant can bow
 1166 the head forward to open up a gap between the cranium and the atlas. The ultrasound beam is
 1167 directed toward this gap when the patch is attached to the suboccipital window.

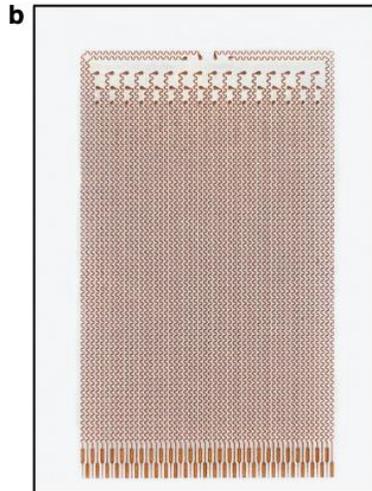

1168
 1169 **Supplementary Fig. 5 | Schematic ultrasound fields of different beamforming strategies.** By
 1170 using different time-delay profiles, the transducer array can transmit focused, plane, and diverging
 1171 waves. The focused waves have an ultrasound beam at a local region of the cerebral vascular
 1172 network. The plane waves have a wider ultrasound field than the focused waves, but their
 1173 ultrasound field is still rather limited. The diverging waves have ultrasound fields tunable with the
 1174 view angle. In this work, a view angle of 40° can appropriately insonate the entire cerebral vessels.
 1175 A view angle of 20° is too narrow whereas a view angle of 60° is redundant, spreading the
 1176 ultrasound energy to unneeded areas.

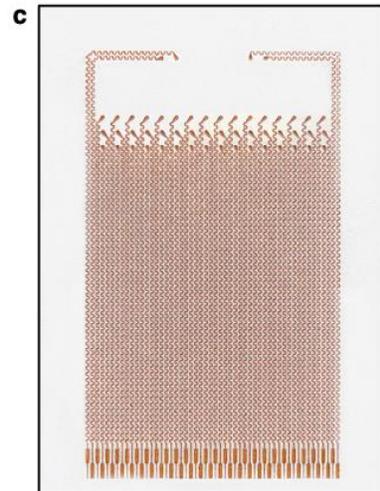

1177
 1178 **Supplementary Fig. 6 | Simulated ultrasound beam steering.** **a**, Ultrasound waves focus at 50
 1179 mm depth with a beam tilting angle of 0°, 5°, 10°, 15°, 20°, 25°, and 30°, respectively. The grating
 1180 lobe is growing and becomes more obvious when the beam tilting angle is larger. **b**, Diverging
 1181 ultrasound waves with a beam tilting angle of 0°, 2.5°, 5°, 7.5°, 10°, 12.5°, and 15°, respectively.
 1182 The simulation was performed using an open-source Matlab toolbox Field II. The medium was set
 1183 as uniform with a sound speed of 1,540 m/s and a density of 1,000 kg/m³. The central frequency
 1184 was 2 MHz, the same as the real probe. We applied the built-in function, “`xdc_2d_array`”, to create
 1185 the transducer array. The transmitted waveform from each transducer element could be set to be a
 1186 focused beam or a diverged beam. All simulation results share the same scale bars.

Supplementary Fig. 8 | Characterizations of the conformal ultrasound patch. **a**, Phase angle and electrical impedance spectra from 1 MHz to 4 MHz. The center frequency is 2.01 MHz with a phase angle of 11.96°. **b**, The center frequency distribution among the 256 elements of the patch. Inset is its distribution map of the 16 by 16 array. **c**, The electromechanical coupling coefficient of the 256 elements. **d**, Pulse-echo response and corresponding frequency spectra of a typical element. The measured -6 dB bandwidth is 17.41%. Doppler signal processing requires extracting Doppler shift in the frequency domain. The small bandwidth provides sharper peaks in the frequency domain. Thus, the frequency difference between transmitted and received signals can be calculated more easily. **e**, Crosstalk between adjacent transducer elements for both frequency sweep and

1203 voltage sweep. **f**, Signal-to-noise ratios with and without the copper mesh electromagnetic
1204 shielding layer. Solid circles represent the mean, and error bars are the standard deviation of the
1205 mean ($n = 12$ for **e**; $n = 5$ for **f**; independent samples).

1206
 1207 **Supplementary Fig. 9 | Simulated 3D images of point phantoms for the patch under different**
 1208 **configurations.** When the conformal ultrasound patch is attached to the skin, it may cause
 1209 deformation of the transducer array, which could subsequently result in phase aberration,
 1210 particularly at high frequencies. However, the ultrasound patch operates at a relatively low
 1211 frequency of 2 MHz in this study, which has a much higher tolerance for phase aberration. We
 1212 performed a simulation to illustrate that the skin curvature has a very low influence on the
 1213 beamforming for low-frequency arrays using the Matlab Field II toolbox. We placed a 2 MHz soft
 1214 array on **a**, flat, **b**, concave, and **c**, convex surfaces. The radii of curvature for the concave and
 1215 convex are both 5 cm. A coherent compounding imaging strategy with 5 insonification angles
 1216 and an interval of 5° is used. The simulation phantom comprises 10 points extending from a depth of
 1217 1 cm, with each subsequent point deeper by 1 cm. Simulation results show that for the concave
 1218 array, the shallow points have higher amplitudes, while the deep points have lower amplitudes,
 1219 than the flat array. This is because the concave array emits a more focused sound beam compared
 1220 to the flat array, resulting in higher sound field intensity at a shallower depth. For the convex
 1221 array, the sound beam is more diverged than the flat array. Therefore, the signal amplitudes are a bit
 1222 lower than the flat array, and the reconstructed points are a bit larger. Albeit these differences in
 1223 intensity and resolution, they are still within an acceptable range. The images share the same scale
 1224 bars.

Supplementary Fig. 10 | Schematics show the difference between the rigid probe with bioadhesive hydrogel and the conformal ultrasound patch. a, The rigid BAUS probe²⁸ uses hydrogel as an acoustic couplant, while the top and bottom surfaces have bioadhesive layers to bond the probe, the couplant, and the skin. Because the elastomer membrane encapsulated hydrogel is solid, there are air gaps between the couplant and the skin, particularly at the temporal window where there is a lot of hair. This will result in compromised bonding and suboptimal acoustic coupling, which is a significant drawback for TCD applications. **b,** In contrast, the conformal ultrasound patch employs liquid ultrasound gel as the acoustic couplant, and we use medical tape (e.g., Tegaderm) to secure the soft probe to the skin. This method ensures stable acoustic coupling. While the temporal window is typically used for TCD detection due to its easy access to numerous blood vessels, a comprehensive assessment requires measuring cerebral blood flow from other windows, such as the orbital and submandibular windows. A hydrogel-based probe may find it difficult to conform to these curved surfaces, limiting its efficacy in TCD imaging. However, the conformal patch, with its superior adaptability, shows great promise in providing a more comprehensive approach to different windows for TCD imaging. Moreover, the BAUS probe necessitates a thick layer of hydrogel as couplant for areas of the skin with a large curvature. The thick form factor could interfere with natural skin movements in wearable applications. The conformal patch, by virtue of being soft and thin, does not present such restrictions. Last but not least, it's crucial to acknowledge that a rigid ultrasound sensor, due to its comparatively simpler circuitry, only offers two-dimensional imaging, which restricts its capability to adequately capture the intricacies of the 3D arterial network in the brain. As different operators may acquire signals from diverse segments of this complex network, the repeatability and reproducibility of results could be compromised. In contrast, the conformal patch facilitates 3D imaging, delivering a more precise and comprehensive visualization of the cerebral vessel network, thereby significantly enhancing the reliability and consistency of the measurements.

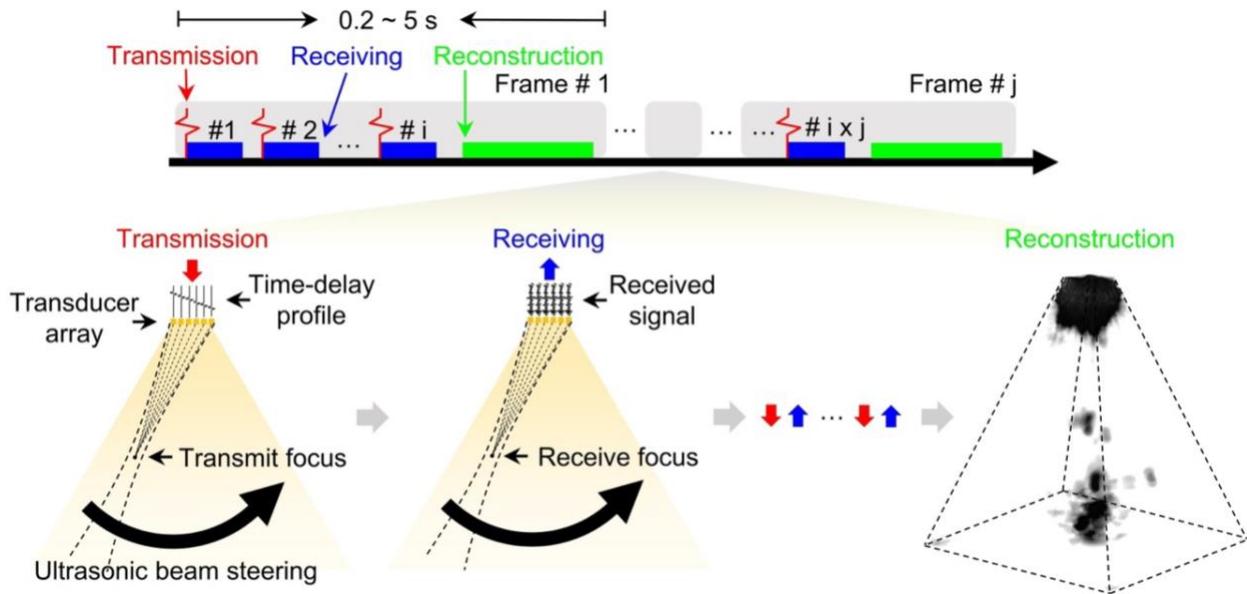

1252
 1253 **Supplementary Fig. 11 | Ultrasound field mapping.** These are the experimentally measured
 1254 sound fields for different situations. Verasonics system drove the transducer array to emit a focused
 1255 beam at a depth of 50 mm. The transmitted acoustic waves were received by a hydrophone (HNP-
 1256 0400, ONDA), digitized by an oscilloscope (PicoScope 5000, Pico Technology), and then
 1257 visualized by software (Soniq version 5.3.1.0, ONDA). A 3D scanning system (AIMSIII, ONDA)
 1258 mapped the spatial distribution of the acoustic beam. **a-b**, The ultrasound intensity distribution of
 1259 diverging waves at 50 mm depth with and without the skull, respectively. The mapping results
 1260 share the same scale bars. **c-d**, The ultrasound intensity distribution of focused waves at 50 mm
 1261 depth with and without the skull, respectively. The mapping results share the same scale bars.

 1271 **independent samples). FFC, flat flexible cable.**

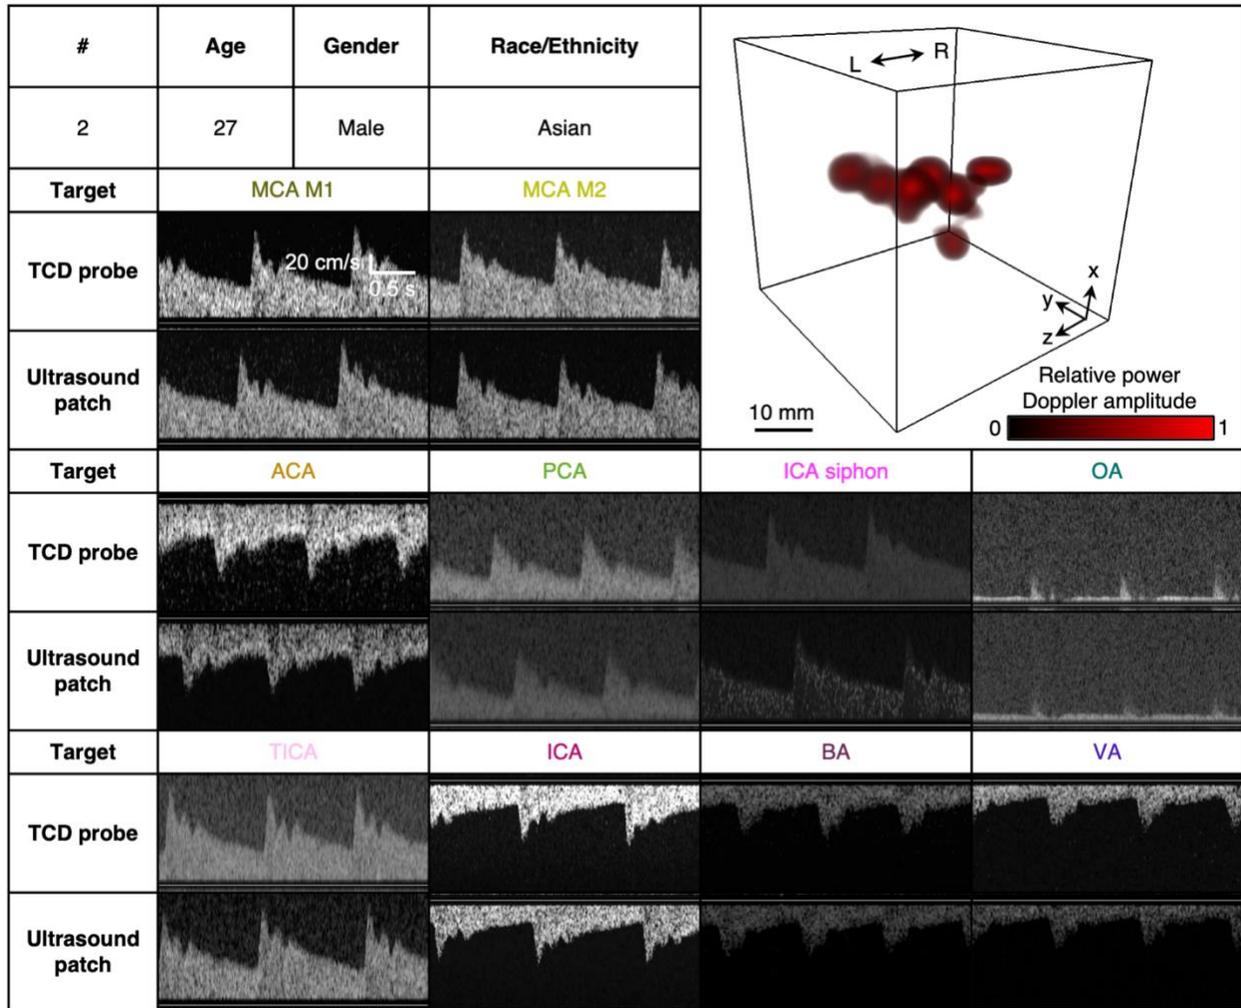

1272
 1273 **Supplementary Fig. 13 | Temporal windows.** **a**, Three windows on the temporal bone used for
 1274 TCD sonography in this work. The middle window is cephalad to the zygomatic arch and
 1275 immediately anterior and slightly superior to the tragus of the ear conch. This window is usually
 1276 the most promising examination site. The anterior window is located more frontally. The posterior
 1277 window is immediately cephalad and slightly dorsal to the middle window. Although all three
 1278 windows can be utilized, physiological differences among participants should be considered when
 1279 selecting one of the temporal windows for TCD sonography. **b-d**, Optical images of the device on
 1280 the middle, anterior, and posterior windows, respectively. Considering the relatively flat surface
 1281 above the entire temporal bone and large curvature tolerance of low ultrasound frequencies (e.g.,
 1282 2 MHz in this work), the influence of surface curvature on beamforming is negligible. Therefore,
 1283 the device can be simply attached to any temporal windows without applying any phase aberration
 1284 correction. The Tegaderm boundaries are labeled by white dashed lines. The optical images share
 1285 the same scale bar.

Supplementary Fig. 14 | Process of conventional ultrasound imaging. To show one frame of image, the conventional probe should transmit and receive signals multiple times by using mono-focus ultrasound beams at different positions in the field of view. After the ultrasound beam is steered to scan the entire field of view, all of the data will be used for image reconstruction. The total time to get one frame of volumetric image is 0.2 to 5 s.

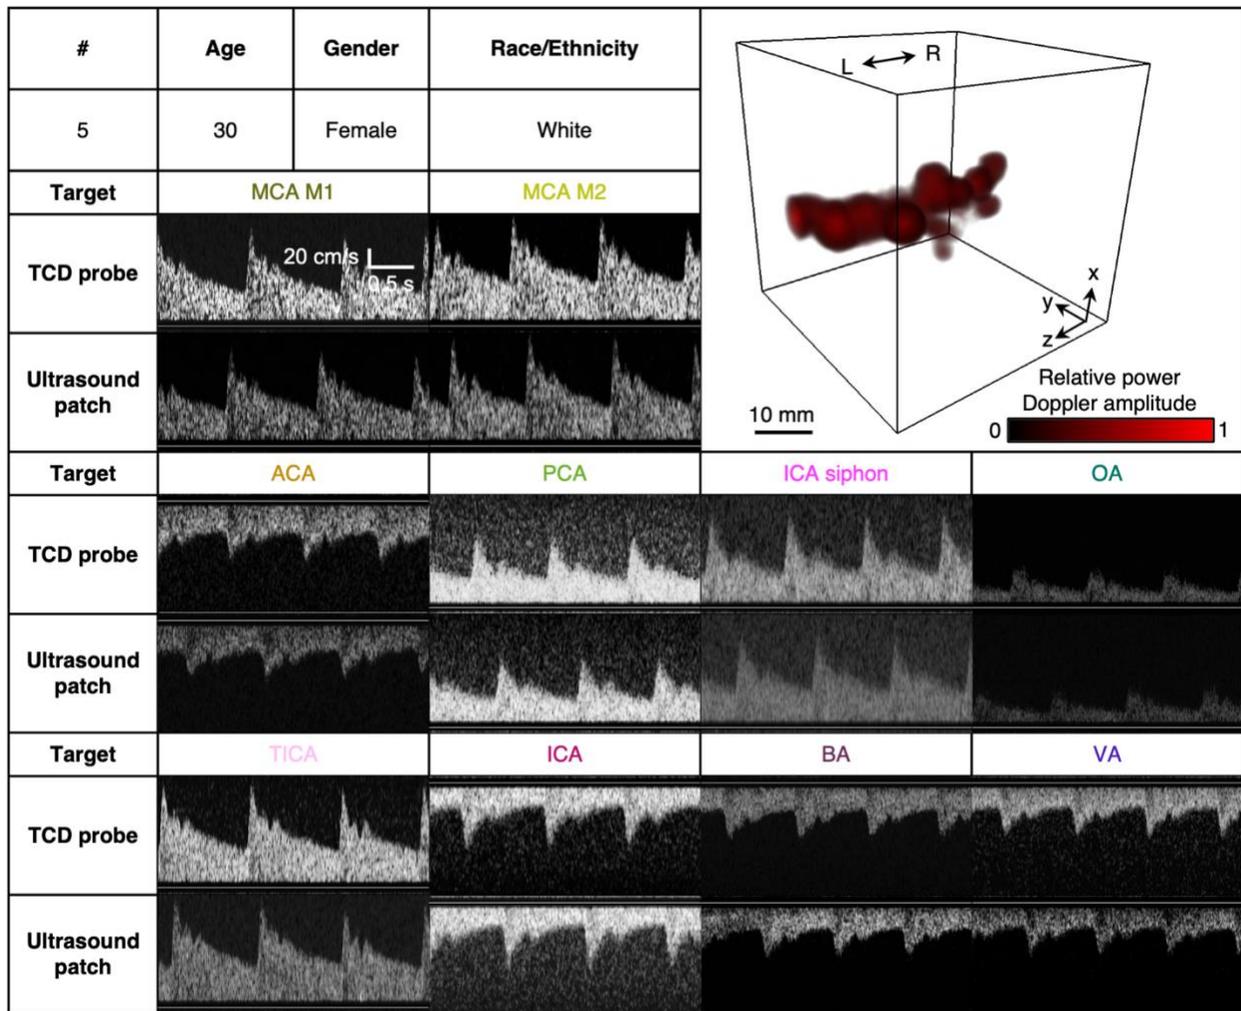

1292
1293 **Supplementary Fig. 15 | Volumetric image and blood flow spectra from participant #2.** The

1625
 1626
 1627
 1628
 1629

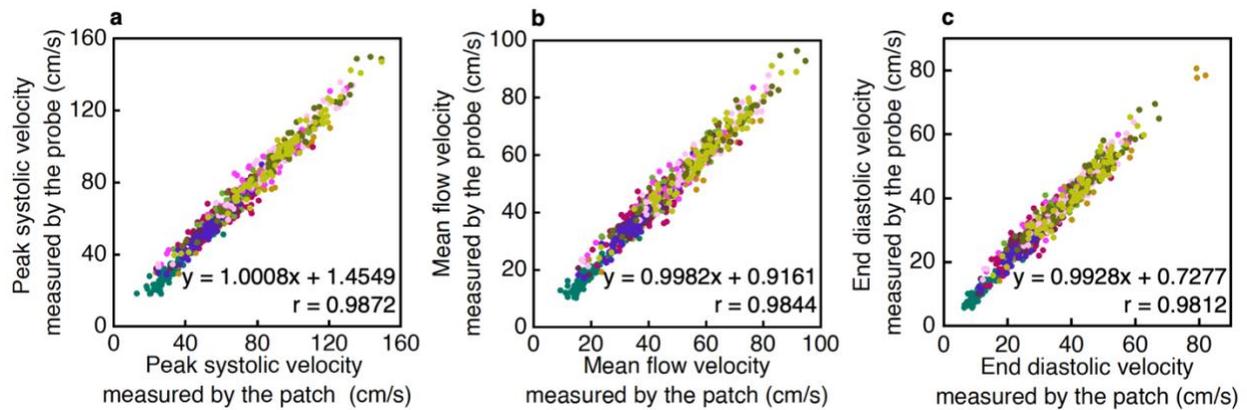

Supplementary Fig. 50 | Analysis of the spectrum in different cardiac phases. The cerebral blood flow spectrum by the conformal ultrasound patch and the electrocardiogram by two electrodes are recorded simultaneously. Different phases in these two waveforms can be correlated. S, systole. D, diastole. ECG, electrocardiogram.

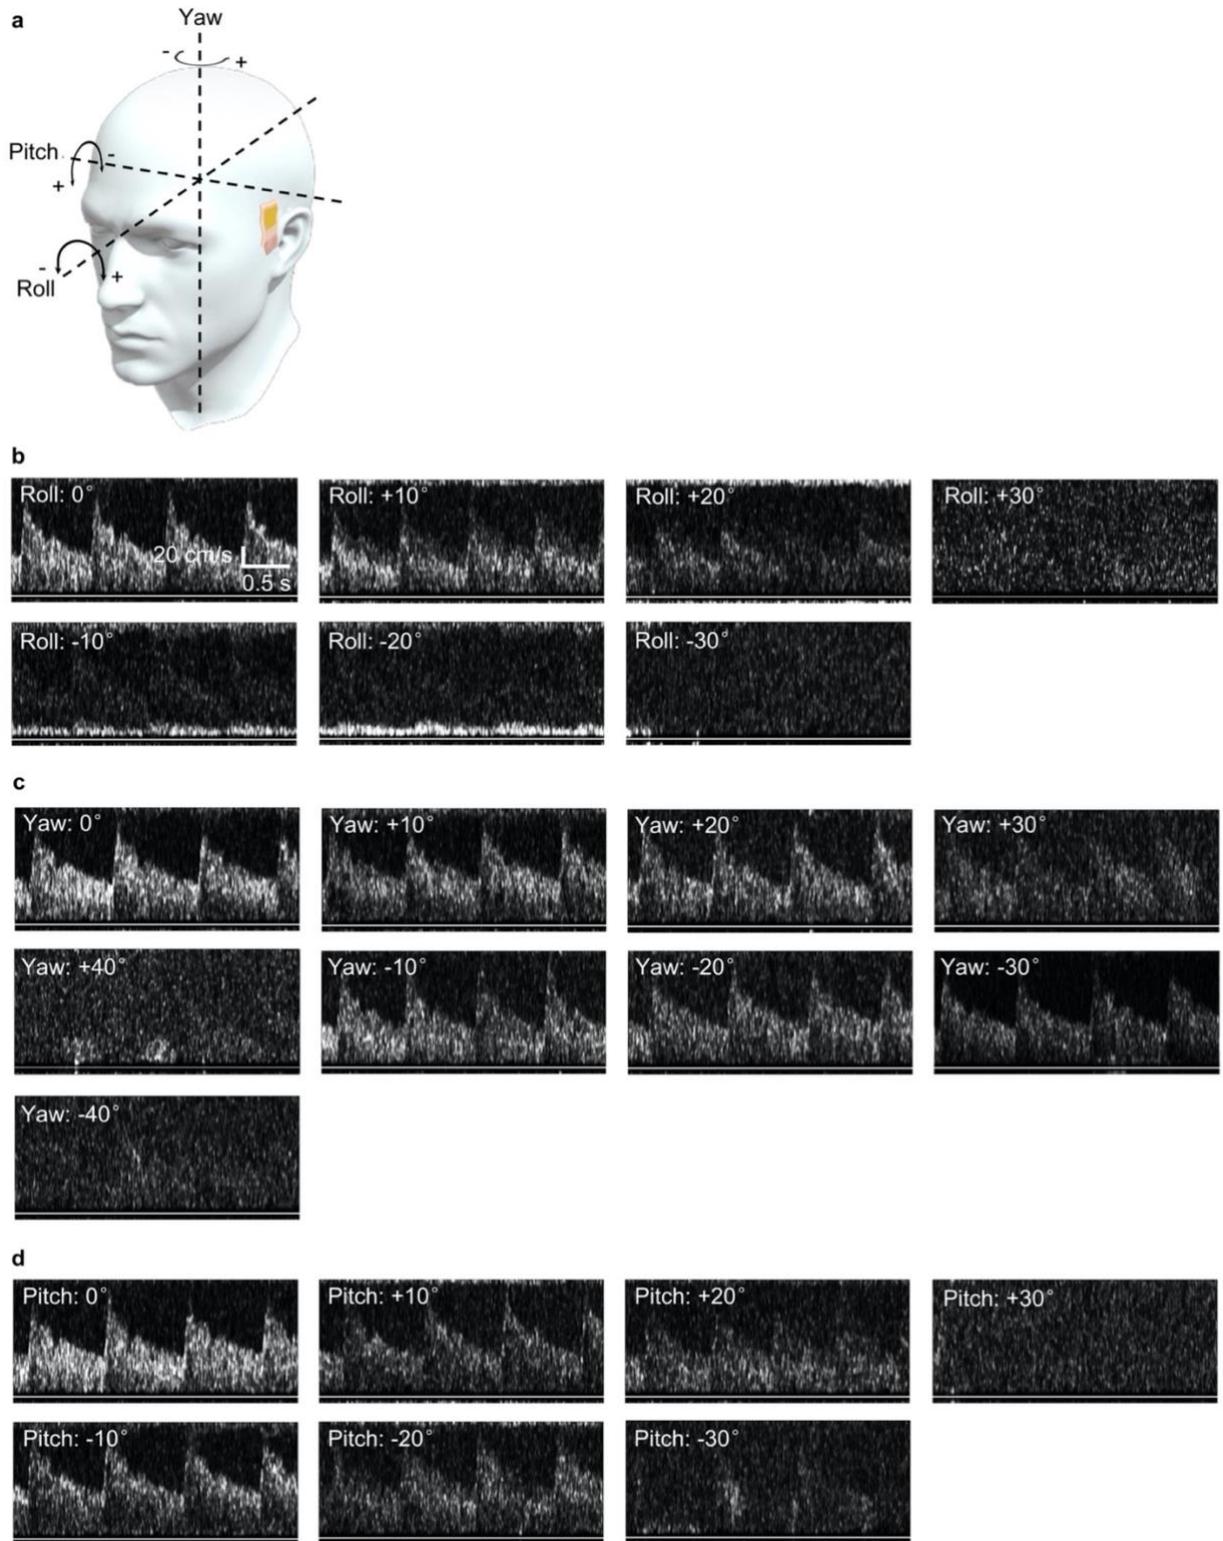

1630
 1631 **Supplementary Fig. 51 | Sample volume optimization.** The comparison of blood flow spectra
 1632 from different sample volumes. The 0D sample volume (single pixel, around $0.77 \times 0.77 \times 0.77$
 1633 mm^3) only contains partial blood flow distributions, while the 3D sample volume (216 pixels,
 1634 around $4.62 \times 4.62 \times 4.62 \text{ mm}^3$) contains the entire blood flow distributions of the target blood
 1635 vessel segment. For patients with cerebral arterial diseases such as stenosis, the turbulence flow
 1636 pattern may happen in the zone of low frequency shift (i.e., low blood flow velocity), which can
 1637 be seen only if an appropriate 3D sample volume is selected. The spectra share the same scale bars.

1638
 1639 **Supplementary Fig. 52 | Statistical analysis of the pulsatility index and resistive index.** Bland-
 1640 Altman plots of **a**, pulsatility index, and **b**, resistive index measured by a conventional TCD probe
 1641 and the conformal ultrasound patch on all 36 participants. Solid blue lines are the mean differences
 1642 of the measurements between the two modalities. Solid red lines are 95% limits of agreement (i.e.,
 1643 1.96 standard deviations above and below the mean differences). Black dashed lines are the zero
 1644 difference of the measurements between the two modalities. The small mean difference and
 1645 standard deviation of the difference suggest a strong agreement between these two sensing
 1646 modalities. Scatter plots of **c**, the pulsatility index, and **d**, the resistive index measured by a
 1647 conventional TCD probe and the conformal ultrasound patch. The linear regression equations and
 1648 Pearson correlation coefficient r is labelled in each plot. Both of the Pearson correlation
 1649 coefficients are larger than 0.9, indicating a strong correlation between the pulsatility index and
 1650 resistive index measurements from the two modalities. Each plot has 762 data points that are color-
 1651 coded for different arterial segments (i.e., cider for ACA, dark cyan for OA, xanthic for MCA M2,
 1652 juniper for MCA M1, boysenberry for BA, blueberry for VA, hibiscus for ICA, kelly green for
 1653 PCA, magenta for ICA siphon, and carnation pink for TICA). SD, standard deviation. r , the
 1654 Pearson correlation coefficient.

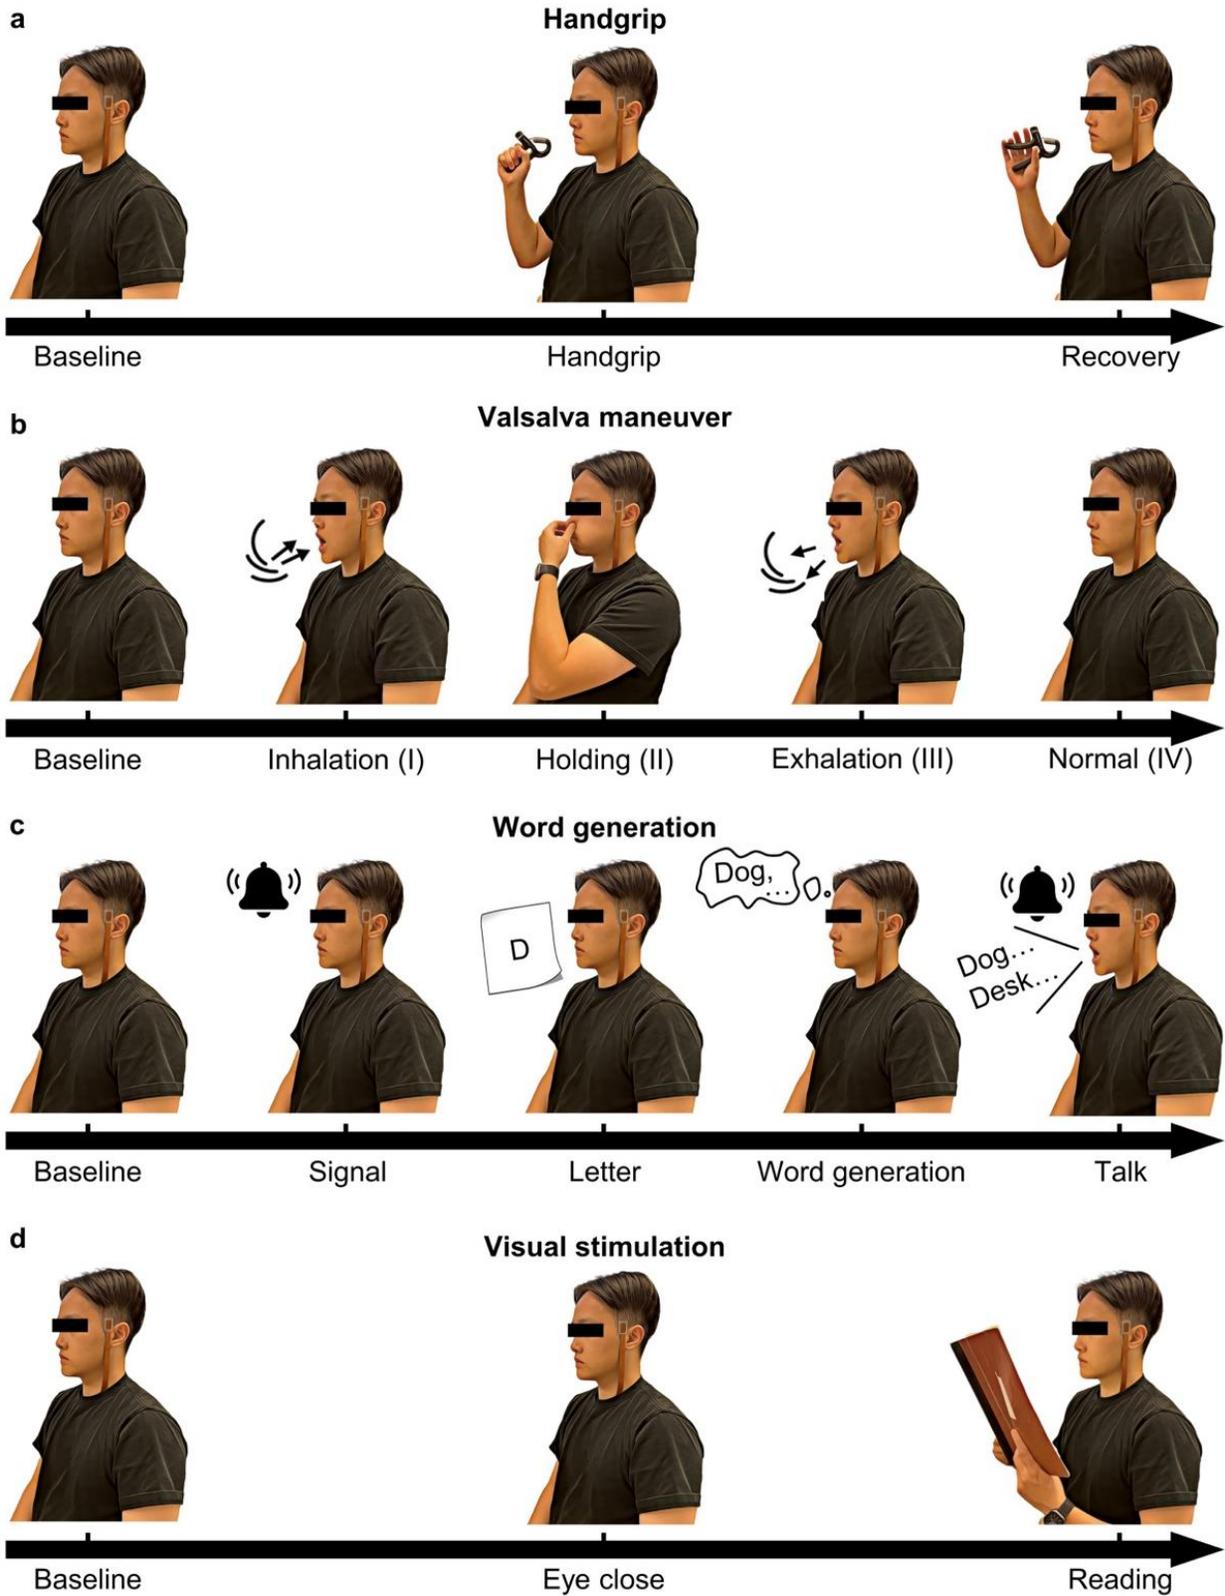

1655
 1656 **Supplementary Fig. 53 | Correlation analysis of blood flow velocity measurements.** Scatter
 1657 plots show a comparison between a conventional TCD probe and the conformal ultrasound patch
 1658 in measuring **a**, peak systolic velocity, **b**, mean flow velocity, and **c**, end diastolic velocity on all
 1659 36 participants. The linear regression equations and Pearson correlation coefficient r for each set
 1660 of data are displayed within each respective plot. The high Pearson correlation coefficients indicate
 1661 a strong correlation between blood flow measurements made by the conventional TCD probe and
 1662 the conformal ultrasound patch. Each plot has 762 data points that are color-coded for different
 1663 arterial segments (i.e., cider for ACA, dark cyan for OA, xanthic for MCA M2, juniper for MCA
 1664 M1, boysenberry for BA, blueberry for VA, hibiscus for ICA, kelly green for PCA, magenta for
 1665 ICA siphon, and carnation pink for TICA). r , the Pearson correlation coefficient.

The rotation may result in relative movements between the patch and the scalp because of the ultrasound gel at

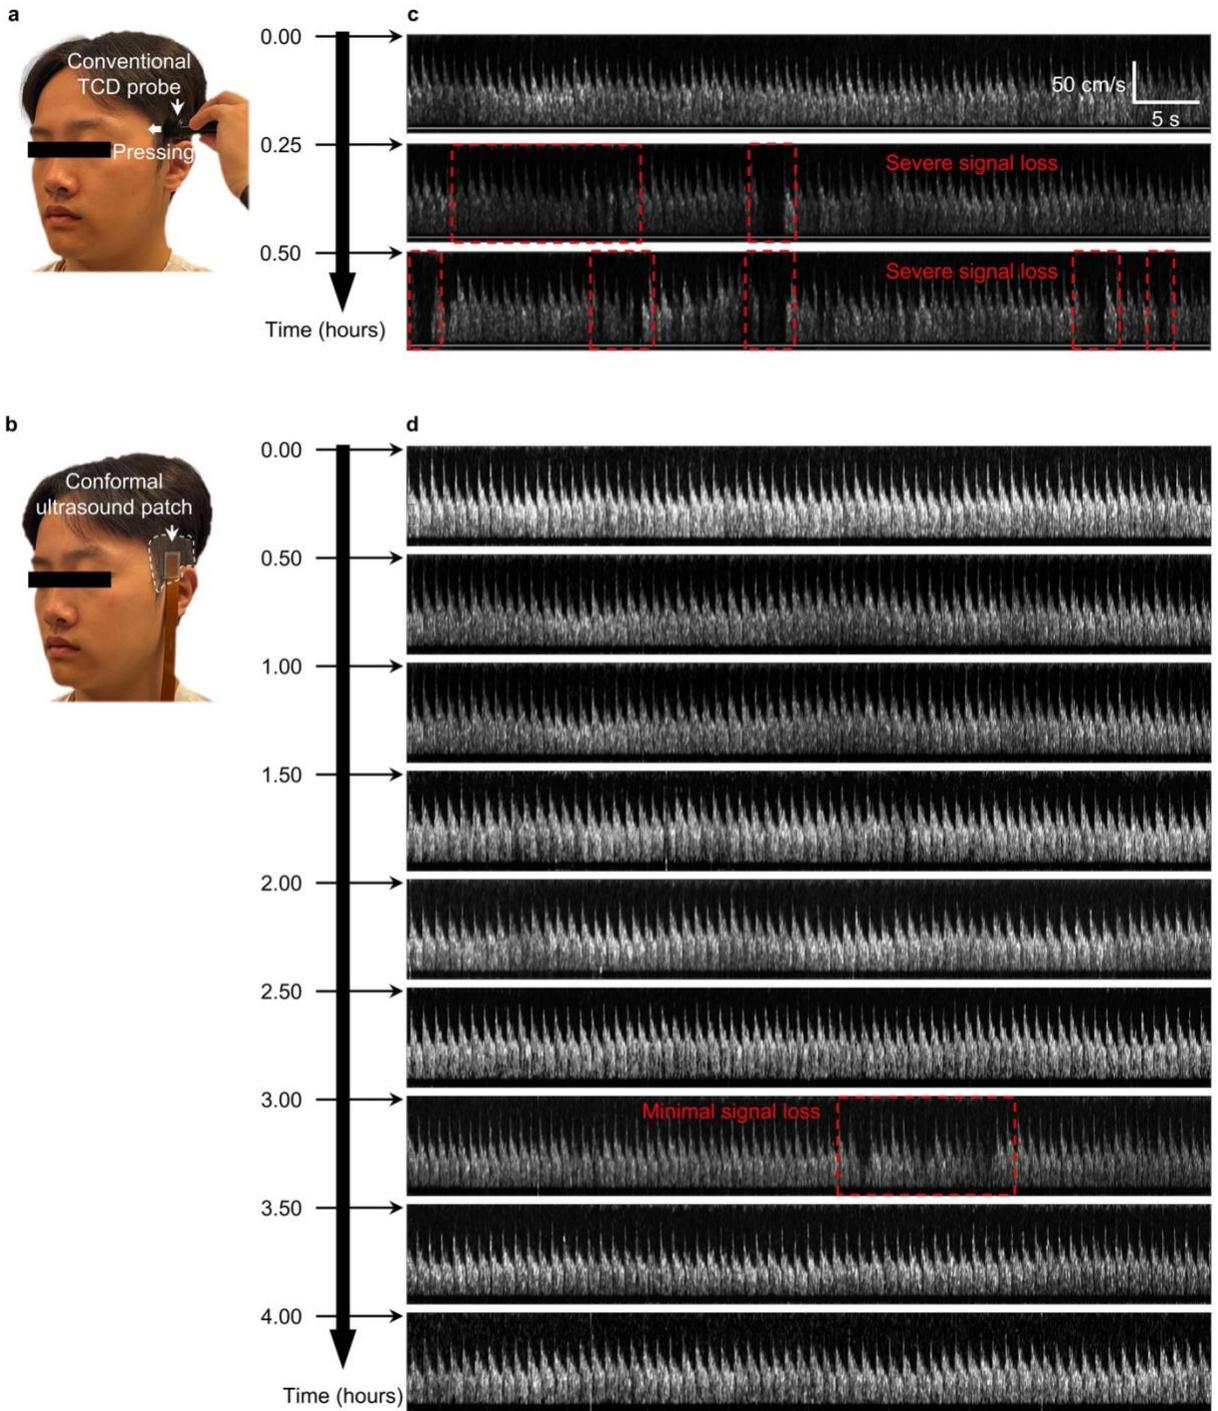

- 1671 the interface. The relative movements lead to gradual signal loss when the rotation angle increases.
- 1672 The conformal ultrasound patch can tolerate a larger degree of yawing than rolling and pitching.
- 1673 The spectra share the same scale bars.

1674
1675
1676
1677

Supplementary Fig. 55 | Activities for altering cerebral flow. **a**, For handgrip, the participant performed baseline recording, handgrip exercise, and recovery. The recorded left MCA is contralateral to the gripping right hand. **b**, For Valsalva maneuver, the participant performed

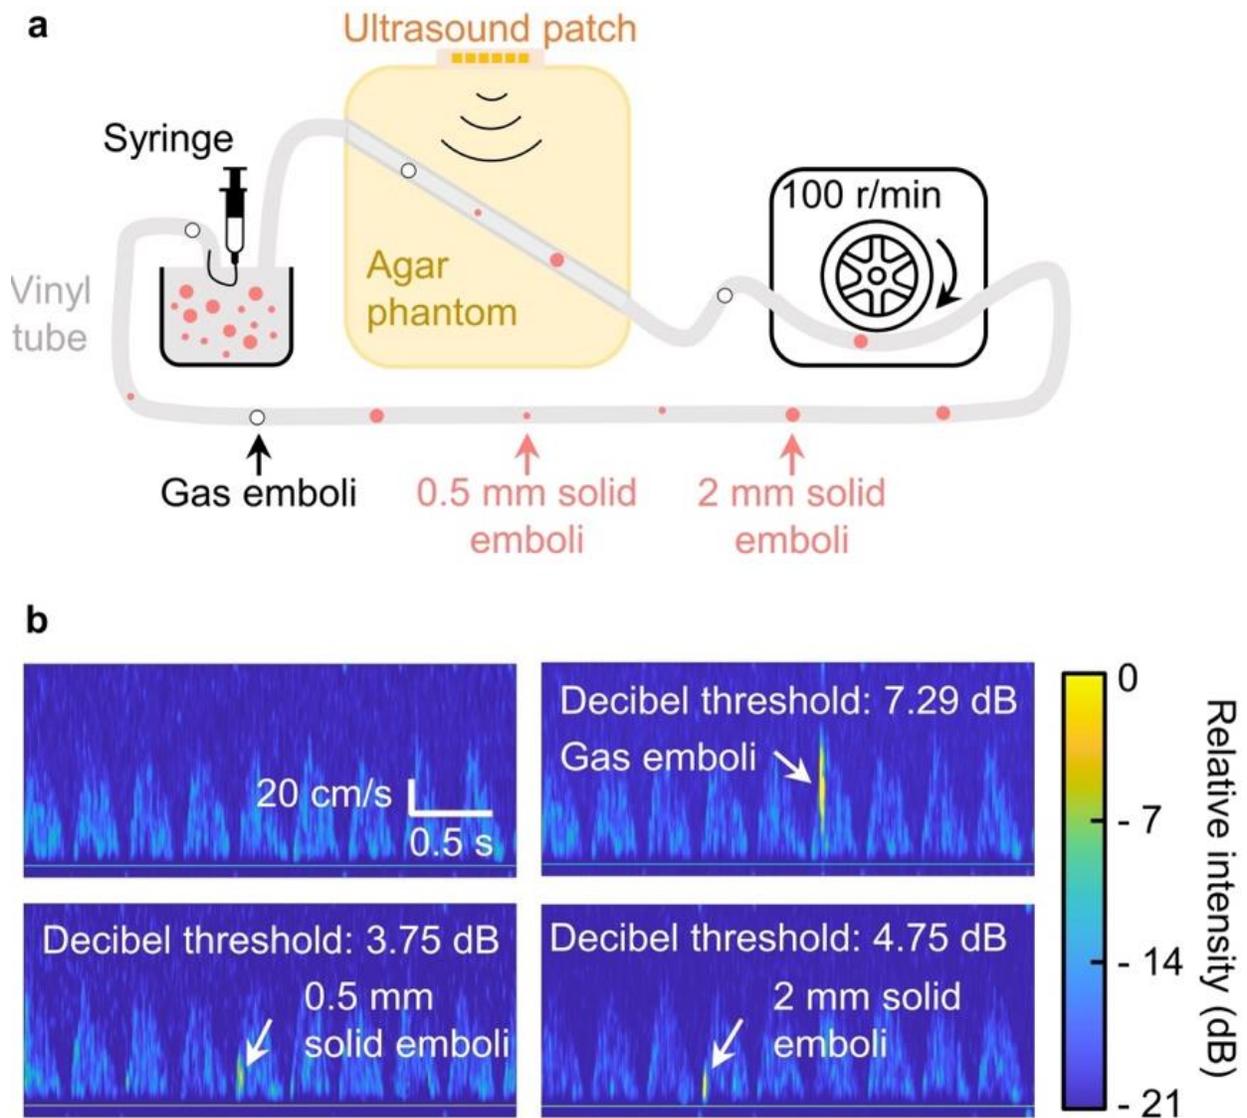

1678 baseline recording, deep inhalation, breath holding, exhalation, and normal breathing. The left
1679 MCA is recorded during the entire activity. **c**, For word generation, after baseline recording, the
1680 participant was cued by tone stimulation, given a letter, asked to make up as many words as
1681 possible using the given letter, and asked to orally report them after a second auditory signal. The
1682 left MCA is recorded during the entire activity. **d**, For visual stimulation, the participant performed
1683 baseline recording, eye closing, and reading a news magazine. The left PCA is recorded during the
1684 entire activity.

Supplementary Fig. 56 | Long-term MCA spectra recording. **a-b**, Operational setups of a conventional TCD probe and the conformal ultrasound patch. The conventional TCD probe needs to be manually held. Pressing is required on the probe-skin interface, whereas the ultrasound patch can conform to the skin with Tegaderm. The Tegaderm boundary is labeled in a white dashed line. **c**, 30 min continuous monitoring of the MCA spectra by the conventional TCD probe. 1 min spectra are shown every 15 min. There are periods with severe signal loss during relative movement between the head and the probe. The spectra share the same scale bars. **d**, 4 hours

1693 continuous monitoring of the MCA spectra by the conformal ultrasound patch. 1 min spectrum is
1694 shown every 30 min. The ultrasound patch can conform to the transcranial windows with minimal
1695 displacement between the device and target arteries. As a result, the patch can tolerate considerably
1696 more motion than its conventional counterpart. The spectra share the same scale bars.

Supplementary Fig. 57 | Conformal ultrasound patch for emboli detection on phantom. a, Schematic experimental setup. Three different types of emboli are used, including gas emboli, 0.5 mm solid emboli, and 2 mm solid emboli. **b,** Flow spectra of baseline, with gas emboli, with 0.5 mm solid emboli, and with 2 mm solid emboli, respectively. The spectra share the same scale bars.

Considering your experiences with both the conventional transcranial Doppler probe and the conformal ultrasound patch, which device did you find more comfortable?

- Conformal ultrasound patch
- Conventional transcranial Doppler probe
- Similar

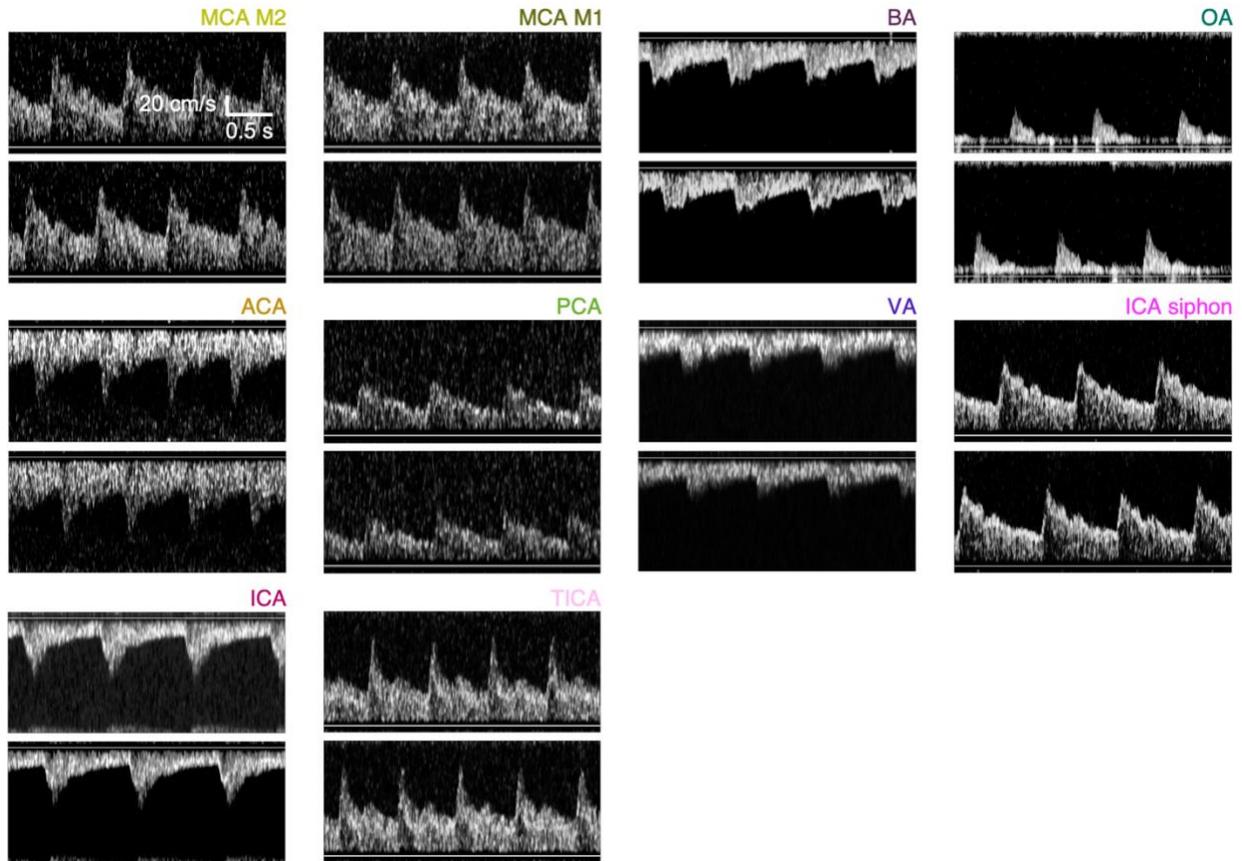

1702
1703 **Supplementary Fig. 58 | Survey of users' experience.** Comparison of comfort levels between
1704 the conformal ultrasound patch and the conventional TCD probe based on participant feedback.
1705 Out of the 36 participants, 69.4% (25) found the conformal patch more comfortable, 25% (9) found
1706 both devices equally comfortable. Notably, the 5.6% (2 participants) who preferred the TCD probe
1707 felt discomfort from tape removal associated with the ultrasound patch. The duration of
1708 measurement by the conventional TCD probe was about 15 minutes for the majority of participants.
1709 An extended duration of measurement with the conventional TCD probe may increase the
1710 preference for the conformal ultrasound patch, as the latter potentially offers greater comfort over
1711 longer periods of utilization.

Supplementary Fig. 59 | Characterization of flow in an arterial phantom. We pumped Doppler fluid (769DF, CIRS) through a Doppler flow phantom (ATS 523A, CIRS) with 4 mm in diameter at an approximate depth of 60-80 mm. The figure shows volumetric flow imaging results from the ultrasound patch alongside the ground truth obtained by a commercial ultrasound probe (e.g., a P4_2v phased array probe) using duplex mode (B mode and power Doppler mode) imaging. **a**, A volumetric image of the flow in the phantom captured by the ultrasound patch. **b**, The ground truth collected by the commercial ultrasound probe. These results demonstrate that the vessel structure measurement from the ultrasound patch is consistent with that from conventional imaging devices, validating its accuracy in capturing blood flow dynamics. L, left. R, right.

1722
 1723 **Supplementary Fig. 60 | The comparison of blood flow spectra measurements.** The
 1724 measurements were taken by a clinically qualified ultrasonographer (i.e., A. Lam) with more than
 1725 30 years of experience in TCD (upper spectra) and S. Zhou (lower spectra) on all different target
 1726 arterial sections by using a conventional TCD probe. All side-by-side comparison datasets
 1727 illustrate similar waveforms and spectral properties, reinforcing the reliability and the accuracy of
 1728 the measurements made by S. Zhou. The spectra share the same scale bars.

Supplementary Fig. 61 | Baseline shifting and aliasing prevention. Once a signal is sampled below the Nyquist rate, the under sampled signals result in an inability to record direction and velocity accurately, which is known as the aliasing effect. For ACA and MCA M2 spectra monitoring, the baselines labelled by the red dashed boxes can be shifted **a**, up and **b**, down to prevent the aliasing effect labelled by the orange dashed boxes. The spectra share the same scale bars.

Ischemic cerebrovascular diseases	Peri-procedural / operative procedures	Neurological / Neurosurgical intensive care	Others
Microembolus detection	Cerebral thrombolysis in acute stroke	Vasospasm after subarachnoid hemorrhage	Pharmacologic vasomotor testing
Sickle cell disease	Carotid endarterectomy	Raised intracranial pressure	Cerebral autoregulation
Right to left cardiac shunts	Carotid angioplasty and stenting	Head injury	Functional TCD for brain activity mapping
Intra and extra-cranial arterial stenocclusive disease	Coronary artery bypass surgery	Cerebral circulatory arrest and brain death	Preeclampsia
Arteriovenous malformations and fistulas	Heart surgery	Intracerebral aneurysm and parenchymal hematoma detection	Liver failure/Hepatic encephalopathy
Internal carotid artery stenosis	Coronary angioplasty		
Acute brain infarction			

1736 **Supplementary Table 1 | Applications of TCD sonography.** The existing applications of TCD
1737 sonography includes diagnosing ischemic cerebrovascular diseases, monitoring in peri-
1738 procedural/operative procedures, neurological/neurosurgical intensive care, and many others. The
1739 conformal ultrasound patch demonstrated in this work holds implications for all of these
1740 applications.

Windows	Targets	Depth (mm)	Velocities (cm/s)	Directions
Temporal	ACA	60-75	50 ± 11	Away
	MCA M2	30-65	55 ± 12	Toward
	MCA M1	30-65	55 ± 12	Toward
	PCA	60-70	40 ± 10	Bidirectional
	TICA	55-65	39 ± 9	Toward
Orbital	OA	45-55	20 ± 5	Toward
	ICA Siphon	60-80	45 ± 15	Bidirectional
Submandibular	ICA	30-60	37 ± 9	Away
Suboccipital	BA	80-100	41 ± 10	Away
	VA	60-80	38 ± 10	Away

1741 **Supplementary Table 2 | TCD sonography protocols used in this work.** The protocols are
1742 summarized according to the transcranial window for each cerebral vessel, depth range of the
1743 target vessel, corresponding mean flow velocity, and flow directions in these cerebral artery
1744 segments relative to the device.

1745 **Supplementary Video 1 | 25 s of MCA blood flow spectrum recording with audio.** The audio
1746 play can be used for training new sonographers and diagnosing diseases (e.g., bruits and murmurs
1747 in stenosis^{48,144}, and chirps and beeps in embolism¹⁴⁵).
